# ACKNOWLEDGMENTS

The authors gratefully acknowledge the contributions of several individuals and institutions in making this encyclopedia a reality. Frank K. Darmstadt, executive editor, worked closely and with unfailing energy on all phases of the project from proposal to production. The late Max Gartenberg, literary agent, helped to organize the project and the contract. Reviews by Carol Sailors greatly improved early versions of the manuscript, and Suzie Tibor did an outstanding job obtaining photographs. The Facts On File graphics department produced the excellent figures from scrap art sketches. The Web sites and resources of the U.S. Environmental Protection Agency, U.S. Geological Survey, National Institutes of Health, Centers for Disease Control and Prevention, International Association for Research on Cancer, and World Health Organization, among others, provided excellent sources of information for this encyclopedia.

Alexander Gates wishes to thank Rutgers University–Newark, which provided numerous library and Internet resources as well as facilities that made this book possible. David Valentino, professor at

the State University of New York at Oswego, suggested several case studies and was always available to give feedback on ideas. Gates's son Colin helped to assemble and produce several of the appendixes. He also wishes to acknowledge his sons Colin and Thomas who put up with their father's having his nose buried in the computer night after night.

Robert Blauvelt gives a special acknowledgment to James G. Cline, who taught him the meaning of a crisp sentence and has been a strong positive influence throughout his career. Anthony Kaufman often served as a sounding board and wellspring of ideas, especially during the developmental stages of the work. Joanne Munkelt contributed several key concepts regarding organization and structure and also provided much-needed periodic motivational impetus. Blauvelt also wishes to thank his wife, Donna, who could not have been a better helpmate and cheerleader. His three children, Andy, Allison, and Stacy, never failed to inspire and delight him. The largest thank-you goes to his mother and father, who instilled in all their children an uncompromising work ethic and strong moral framework.

# INTRODUCTION

The idea for this encyclopedia began with an invitation made to an environmental professional to give a short talk on careers in the environmental industry to an introductory college class at Rutgers University. Robert Blauvelt had the class on the edge of its seat with his stories about dangerous industrial waste affecting residential water supplies, in many cases with criminal intent. The students were so interested that they asked him to return. Considering what a crucial role the environment plays in modern society, and indeed in our very survival as a race, it is important that there be a resource for these students and all of the other concerned people in the world.

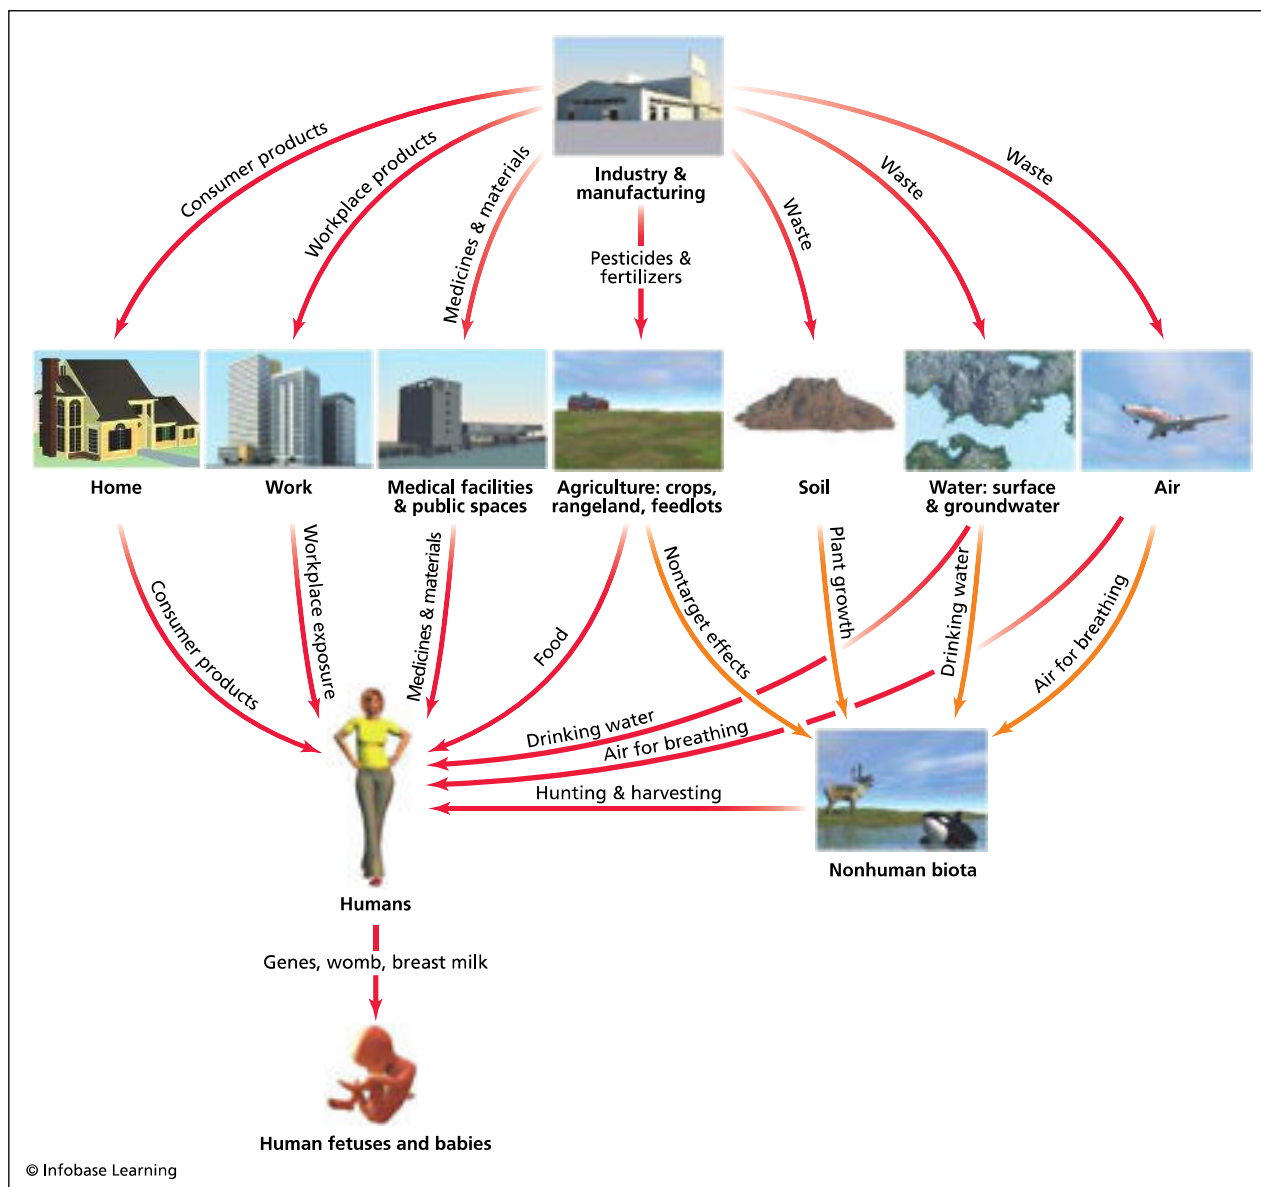

*Encyclopedia of Pollution* is a two-volume set designed to address all aspects of pollution and the entire environmental profession. It is a sourcebook for learning about many different types of pollutants, including properties, production, uses, environmental release and fate, adverse health response to exposure, and environmental regulations on human exposure using the most current scientific data. It provides the scientific background on the water, soil, and air of environments where the pollutants are released. Such environments include terrestrial areas such as streams, wetlands, deserts, glaciers and glaciated areas, and karst terrains, among others, and the soils and water-bearing bodies within these areas. Marine areas include beaches, deltas, and deep marine settings. The processes of the atmosphere, including fronts, hurricanes, and tornadoes, are also addressed as background settings. Pollution regulation and the function of federal regulatory agencies as well as environmental advocacy groups are also described. Finally, the technology and methods to reduce pollution and to remediate existing pollution problems are reported.

These background areas certainly serve as standalone resources for anyone who wishes to investigate any of these areas. This is especially true for details about individual pollutants that are not available elsewhere in a single resource that is readily acces-

sible to a layperson. The background, however, also serves to support the numerous case studies and essays in this compilation. Numerous examples of pollution of all three media—air, soil, and water—are included. These case studies are of the most infamous of pollution events, such as the *Deepwater Horizon* oil spill, the *Exxon Valdez* oil spill, the Gulf Storm oil well fires, the Chernobyl disaster, Hurricane Katrina, the World Trade Center disaster, and Love Canal, New York, among many others, but also include many examples of pollution that might be more obscure but that had great impact on legislation or that were used in popular media, such as the films *Erin Brockovich* and *A Civil Action*, among others. With this encyclopedia, the disaster can be read about, and all of the background—the pollutants, the environmental setting, the applicable legislation, and the remedial technologies—within the case study are readily available for elucidation. This design is intended to give the reader the maximal understanding and appreciation of the pollution event. There are also several biographies of some of the leaders and pioneers of pollution study and environmental activism.

This encyclopedia is arranged in alphabetical order for ease of retrieval if the name of the entry is known. A cross-referencing system is also included on pages xi–xiii for readers who wish to research a specific topic. Entries are categorized into air pollution, water pollution, soil pollution, organic pollutants, inorganic pollutants, pesticides, biological, and biographies. There are summary entries for air pollution, water pollution, soil pollution, organic pollutants, inorganic pollutants, and pesticides that provide an overview of the issues and challenges within each category. These are intended to be a starting point and context for the specific case studies in the group. There are many other ways the entries could be cross-referenced, and there are overview entries on these as well. For example, agriculture and pollution, mining and pollution, and oil spills/offshore oil production could be additional

**A flowchart showing how synthetic chemicals are generated by industry and passed through a number of paths to ultimately affect humans. (Nonhuman biota is also affected by these chemicals.) Although these chemicals typically reach humans and biota in very small amounts, the cumulative effect of this exposure on health is unknown.**

headings under which the entries are subdivided. Rather than generate numerous lists of the same group of entries, only one group of lists is presented.

The final features of this encyclopedia to promote understanding and full appreciation of the issues are several useful appendixes. These include a very detailed glossary to explain unfamiliar words and a list of standard abbreviations for the environmental profession. There are several standard indexes for air and water quality and current rankings of pollutants

and the annual amount released to the environment. There is a time line to put events into historical perspective and these are rankings of major oil spills by volume released, also to provide perspective. Finally, there are tables for Superfund sites and the chemicals present. Superfund sites are the most profoundly polluted places in the nation, requiring direct government intervention to protect environmental and public health. Most of the land-based case studies are or were Superfund sites.

# ENCYCLOPEDIA OF POLLUTION

# A

**acid mine drainage (AMD)** Minerals that contain iron, lead, copper, or other metals form the industrial base for most of the world's economies. The extraction, processing, and refining of these minerals, if not done properly, can have adverse environmental consequences. One of the problems that can be caused by poorly implemented mining procedures occurs if water interacts with the sulfur compounds that are often present in the mined ores or waste rock and forms acid mine drainage, a low pH (acidic) solution that can enter nearby surface water bodies and severely damage the ecosystem.

Many mineral deposits contain sulfides, or minerals that include sulfur as the anion (negative atom) in the compound. These sulfides can be economically valuable if the metal in the ore is sought after for use in an industrial process or as part of a finished commodity. Sulfides with zinc, copper, and nickel, among other metals or elements, have retained their commercial value, and sulfides with lead and iron were in demand in the past. In some cases, sulfur by itself is a highly valuable material, which is used in sulfuric acid, matches, explosives, or the production of other chemicals. In many cases, sulfides are unwanted components of an ore deposit, occurring as gangue, worthless materials that must be removed before ore extraction or processing can begin, or as accessory minerals, those present in such a minor amount that they are not an important constituent of the ore. As sulfide minerals are not the primary target of mining, they are left in the waste rock if present at concentrations too low to recover for profit. The sulfur undergoes a series of oxidation reactions in the environment to produce sulfurous and sulfuric acid, which concentrates in

surface water runoff if rain comes into contact with the waste rock. The following equations show how pyrite (iron sulfide), the most common sulfide, reacts with water to form acid:

Pyrite reacts with water and oxygen to form ferrous iron and sulfate (sulfuric acid)

Pyrite, ferric iron, and water react to form ferrous iron and sulfate (sulfuric acid)

Sulfate is a negatively charged compound in which a central sulfur atom is surrounded by four oxygen atoms ( $\text{SO}_4^{2-}$ ). Sulfate ions usually are joined with metals such as barium (barite) or calcium (gypsum) and, if present in sufficient quantities, can be economically valuable. Sulfate mineral deposits also may produce acid mine drainage, but it is typically not as severe as that caused by sulfide-bearing rocks. The acidic runoff from waste rock piles that contain sulfide and sometimes sulfate can do significant damage to the environment both by killing plants and animals and by lowering pH and allowing heavy metals to dissolve into the local water. It is for this reason that acid mine drainage is a serious problem in many areas.

## SOURCE AND MECHANICS OF ACIDITY

Sulfide minerals are usually present in rocks and minerals. They are especially common in hydrothermal deposits, where sulfur and some types of metals

are dissolved in superheated water given off by cooling magma. The most common sulfide, pyrite, also known as fool's gold, can occur in most crystalline rock, but it also can be produced by bacterial action in swamps and other depositional environments. It is for this reason that pyrite most often occurs in shale and coal. In shale, the presence of pyrite results in acidic conditions degrading the quality of the water. If sulfide from pyrite is dissolved in groundwater, it can damage the plumbing in a house that uses untreated well water. Pyrite in coal causes a much more serious problem because it is the main contributor to acid mine drainage.

Weathering of rocks over tens of thousands to millions of years gradually removes the sulfur and associated heavy metals and distributes them into the natural environment in such low concentrations that there is little risk to human health or the environment. Most mined material, however, is not composed of the typical stable, weathered minerals on the surface of the Earth; rather, it is highly reactive material rich in elements that can cause adverse ecological impacts. This occurs because during mining, rock with fresh, unweathered surfaces is raised up to ground level and immediately exposed to wind, rain, and varying temperatures, where the sulfur can be chemically liberated and enter the environment much more quickly and at higher concentrations. Weathering rapidly strips out the sulfur to create acid waters, which in turn dissolve the other unstable minerals, releasing the cations (positively charged ions) into the water. These cations are commonly heavy metals such as lead, nickel, mercury, and arsenic that degrade water quality and damage the environment.

An exacerbating factor in this situation is that the rock is broken into small pieces during the mining process. Weathering and the accompanying chemical reactions take place on the surface of rocks. Smooth natural exposures of bedrock at the surface present minimal surface area upon which chemical weathering can take place. Waste rocks from mines have rough textures, which increase surface area. In addition, surface area increases exponentially as grain size decreases as the coal or other types of sulfur-bearing ore are made smaller to facilitate its handling and shipment. This deadly combination of increased surface area and increased reactivity results in waters that have been changed to the acidic component of the waste rock.

Acidic waters are very damaging to aquatic life. Most freshwater lakes, streams, and ponds have a natural pH in the range of 5.6–8 depending on the rock and soil in which the water resides. Acid water has many harmful ecological effects if the pH of

an aquatic system is below 6 and even more if it is below 5. If the pH is between 5.5 and 5, snails and clams are absent, and populations of fish such as smallmouth bass disappear. Bottom-dwelling bacteria (decomposers) die, leaving leaf litter and detritus to accumulate. This locks up essential nutrients and reduces the availability of carbon, nitrogen, and phosphorus for use by other organisms. Mats of fungi start to replace the bacteria on the substrate. Normal plankton disappear, and undesirable species of plankton and mosses may begin to invade the ecosystem. Metals such as aluminum and lead, which are toxic to aquatic life but normally trapped in sediments, are released into the acid water. If the pH drops below 5, fish populations begin to disappear completely. The bottom becomes covered with undecayed material, and mosses spread and grow to cover near-shore areas. Mayflies and many other insects are unable to survive, and most fish eggs will not hatch. If the pH drops below 4.5, the water will become devoid of fish, most frogs, and insects. If the pH is between 3 and 4, fish are unlikely to stay alive for more than a few hours, but some specialized plants and invertebrates can still survive.

### AREAS OF ACID MINE DRAINAGE

By far the largest area in North America affected by acid mine drainage is the eastern, or Appalachian, coal region of the United States. This area encompasses parts of New York, Pennsylvania, Maryland, West Virginia, Virginia, Tennessee, Alabama, Kentucky, and Ohio, although several other belts are similarly damaged. Coal is removed primarily from underground workings in this region, but strip mining is practiced locally as well. Strip mining involves the removal of large volumes of soil and soft rock that overlie a coal seam or bed. Large excavators called drag lines equipped with rotating grinders then are used to cut or remove the coal for loading and further processing at a nearby mill. This process breaks the coal up into very small pieces, sometimes creating dust and making it easy for water to leach or wash the sulfur out of the coal. Most coal, especially coal mined in the eastern United States, has a high sulfur content, and it is easily dispersed over the surrounding area through ore transportation or storage and as windblown dust. All these factors contribute to extensive acid mine drainage in the vicinity, with a pH commonly in the 3–4 range and in some cases below 3. The acidic surface waters near the mines certainly also have a detrimental effect on aquatic organisms and plants, but, fortunately, they do not extend very far from the source. Much of the bedrock in these areas is limestone, which naturally

buffers (raises the pH) the acidic waters. In some cases, however, despite the buffering capacity of the underlying bedrock, the amount and character of AMD are so pervasive that it overwhelms this naturally available neutralization mechanism and results in adverse environmental impacts.

Acid mine drainage from crystalline rocks is less common because there are fewer mines, and they are generally smaller, underground operations. There are some large mining operations in Colorado and other areas of the western United States involving crystalline rocks, but they are generally isolated and in areas of such low population density that, in most cases, they are not reported by the media. There are some abandoned mines in crystalline rocks in the East that still produce acidic waters, but they are small and largely unreported, as well. One mine in the Hudson Highlands of New York produces waters with a pH as low as 1.77, but it is small and isolated.

In cases where ore processing or smelting is done on-site or near the mines, AMD is much more of a problem. In this case, discharges from smelting and processing operations, as well as from tailings and slag, combine and severely stress the local ecology. There are two cases, in Palmertown, Pennsylvania, and Duck Town, Tennessee, where acid fallout from smelters laid waste the area around them. The Palmertown plant processed the zinc sulfides from the Sterling Zinc Mines in Ogdensburg, New Jersey. The ore was taken in by train and processed on-site for many years. As a result, there is still a large swath along the Lehigh River that still will not grow any trees or anything else. Duck Town largely processed lead sulfide and has become a classic example of ecosystem destruction from acid fallout.

**acrolein** Normally, a contaminant requires both a widespread distribution in Superfund sites and toxicity to achieve a high ranking on the 2007 CERCLA Priority List of Hazardous Substances. Acrolein has been identified in only 32 of the first 1,684 current or former U.S. Environmental Protection Agency (EPA)-designated Superfund sites on the National Priorities List, and yet it is ranked the number 37 worst pollutant on the 2007 CERCLA list. This ranking places it among dangerous substances, such as polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and some of the most notorious pesticides. Although it is more common than the Superfund data might suggest, the real danger of acrolein is its extreme toxicity to humans. Acrolein is also known as 2-propenal, acraldehyde, allyl aldehyde, or acryl aldehyde, but it is not widely available to the general public, so there are not many commercial products that contain it.

#### PROPERTIES, USES, AND PRODUCTION

Acrolein is an organic compound that occurs naturally in the burning of some substances but is primarily synthesized. Chemically, it is the simplest form of an unsaturated aldehyde. Acrolein occurs as a clear or yellow liquid with a burned, sweet, and pungent odor. Acrolein evaporates quickly under normal conditions but even faster as temperature increases. It can therefore be classified as a volatile organic compound (VOC). Acrolein is primarily an intermediary in the production of other chemicals. It is used in the preparation of polyester resin, polyurethane, propylene glycol, acrylic acid, acrylonitrile, and glycerol. It is in this capacity that it is fairly widespread, as these are high-volume products. Acrolein may be found in some livestock feed. In contrast, it is also a pesticide that is added to irrigation canals and the water supplies of some industrial facilities to control underwater plant, algae, and slime growth. At much higher concentrations, it is used to make chemical weapons.

Reported annual production of isolated acrolein between 1980 and the early 1990s is moderate relative to that of many other industrial chemicals. The United States produced between 29,700 and 38,500

tons (27,000–35,000 metric tons) per year, while Japan produced an average of 22,000 tons (20,000 metric tons) per year. France and Germany together produced 66,000 tons (60,000 metric tons) per year, and Russia averaged 11,550 tons (10,500 metric tons) per year.

### ENVIRONMENTAL RELEASE AND FATE

Acrolein can enter the natural environment as both a point source and a nonpoint source pollutant. As a point source pollutant, it moves into air, water, or soil near production, transportation, and storage facilities in addition to hazardous waste sites as the result of spills and leaks. Small amounts of acrolein can enter the air as a nonpoint source pollutant if certain trees and other plants, including tobacco, are burned and when fuels such as gasoline and oil are burned. Acrolein also occurs in building fires at concentrations that can be deadly for occupants.

Once in the air, surface water, or soil, acrolein degrades quickly. In air, the primary area of release, it is quickly degraded by reaction with photochemically generated hydroxyl radicals (air pollution). In cleaner air, it can last long enough to be removed by precipitation (washout). The average removal half-life of acrolein in the air is estimated to be less than 10 hours. If released to surface water, acrolein evaporates, breaks down through chemical reactions, or is biodegraded by microorganisms. The removal half-life of acrolein applied as a herbicide in irrigation canals ranges from 7.3 to 10.2 hours for complete removal by evaporation. The overall removal half-life of acrolein in surface bodies of water is estimated to be between 30 and 100 hours depending upon the stream or channel. In streams and rivers degradation is quicker, especially in warm climates, whereas in lakes it is slower, especially in cold climates. In sediment/water systems, acrolein undergoes chemical and biological degradation. Experimental removal half-lives of 7.6 hours were determined for aerobic conditions and 10 days for anaerobic conditions. An overall reactivity-based half-life is estimated to be between 100 and 300 hours.

If released to soil, most acrolein evaporates from the surface. That which penetrates the soil can be fixed to clay and organic particles or can leach into the groundwater. The overall removal half-life of acrolein in soil through chemical breakdown is estimated to be between 30 and 100 hours depending upon the conditions. If it leaches through the soil, acrolein is very persistent in groundwater. Removal half-lives have been estimated at 11 days for aerobic degradation and 336–1,344 hours (14–56 days) for anaerobic degradation.

According to the EPA Toxic Release Inventory (TRI), there were 248,239 pounds (112,836 kg) of acrolein released to the environment by industry in 2005. This quantity is classified as a moderate amount.

### HEALTH EFFECTS FROM EXPOSURE

There are numerous adverse health effects from both acute and chronic exposure to acrolein. For example, it is extremely toxic to humans through inhalation and dermal exposure. Acute exposure through inhalation at levels as low as 10 parts per million (ppm) may result in death in humans. Other effects on the lungs, such as upper respiratory irritation and congestion, occur at very low concentrations. Acrolein is also a strong skin irritant, causing skin burns in humans in both acute and chronic exposure. It results in irritation and tearing of the eyes as well. Animals that ingested acrolein had stomach irritation, vomiting, stomach ulcers, and bleeding. The major effects from chronic, long-term, inhalation exposure to acrolein in humans primarily consist of general respiratory congestion and eye, nose, and throat irritation.

The Department of Health and Human Services (DHHS), the International Agency for Research on Cancer (IARC), and the EPA cannot determine the potential carcinogenicity of acrolein because the current database of scientific studies is inadequate.

### REGULATIONS ON HUMAN EXPOSURE

Several federal regulatory agencies set limits on human exposure to acrolein largely as the result of its extreme toxicity. The EPA has restricted the use of all pesticides containing acrolein and has classified acrolein as a toxic waste. They have set limits on the amount of acrolein allowed into publicly owned wastewater treatment plants. They further require that releases of 1 pound (0.45 kg) or more must be reported to the National Response Center. The Food and Drug Administration requires that levels of acrolein in modified food starch must not exceed 0.6 percent. The Occupational Safety and Health Administration (OSHA) set a limit of 0.1 ppm acrolein in workroom air during an eight-hour workday over a 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) also limits acrolein in workroom air to 0.1 ppm averaged over a 10-hour shift.

**Aegean Sea oil spill Galicia, Spain December 13, 1992** *Water Pollution* The economies of the world's industrialized and developing countries are powered primarily by fossil fuels: coal, natural gas, and oil. A ready supply of these relatively inexpensive sources of energy is needed for electrical generation, internal combustion engines, and basic industrial chemicals (inks, fertilizers, medicines, etc.). Worldwide, 3 billion gallons (13.6 billion L) of oil are consumed every day, with the United States using about 23 percent (700 million gallons [2.65 billion L]). Unfortunately, for a variety of geologic reasons, many fossil fuels, particularly oil, are often inconveniently located in areas remote from industrial centers and end use markets. One of the early problems of the Industrial Revolution, which continues to this day, was how to move the oil from where it is to where it is needed. Transportation of oil from remote regions to areas of need can result in accidents and spills. Compared to the oil released to the oceans from urban runoff, spills related to the operation of military and commercial ships, discharge by industrial activities into the air, and natural processes such as seepage from oil-bearing geologic formations caused by earthquakes or erosion, these spills are minor by volume. Although they account for only 6 percent of the oil released into the ocean, discharges from tanker accidents tend to be more ecologically devastating because they occur suddenly; let loose millions of gallons of oil in a single, often confined

place (harbor, bay, or shoreline); and can destroy sea and shore life and habitat over large distances.

One such incident in which a large amount of oil was spilled involved the tanker *Aegean Sea*. Commissioned in 1973 and operated under Greek registry, the *Aegean Sea* was one of the most modern tankers in the world fleet and, just prior to the accident, passed rigorous safety inspections by both United Kingdom and Spanish maritime authorities.

## THE ACCIDENT AND OIL SPILL

In early December 1992, the Panamax oil transport vessel *Aegean Sea* began its relatively short voyage of approximately 800 miles (1,280 km) from the British Petroleum oil terminal *Sullom Voe* in northeast Scotland to the Repsol oil refinery in La Coruña (A Coruña in Galician), Spain. As the ship neared the Spanish coast, in the area known as Galicia, the weather deteriorated dramatically. Named after an ancient Celtic tribe that inhabited the region, Galicia is on the northwest Iberian Peninsula in Spain, bordering Portugal to the south and the regions of Castile and León to the east. The coastline of this area, extending from the villages of Muros and Noia in the south to La Coruña in the north, has been known since Roman times as the Costa da Morte, or Coast of Death. In fact, the Roman name for the region, Finisterre, or "end of the world," is a tribute and warning to its rugged, untamed character. Directly facing the Atlantic Ocean, this part of the Galician coastline has no sheltering islands or bays. Sailing east from Galicia, the next landfall encountered is the east coast of North America. Galicia is a rocky and treacherous area, where the winds and waves can be ferocious and shipwrecks are common.

On December 13, 1992, as the *Aegean Sea* approached the docks of La Coruña near the Repsol oil refinery, sustained winds were more than 60 miles per hour (100 km/h), and visibility was less than 330 feet (100 m). Tanker captains are under enormous pressure from ship owners and operators to make port on schedule. Deliveries often are timed to coincide with expected shifts in oil prices and to maximize refinery output. Despite the terrible weather and the well-known dangers of the coastline, the captain of the *Aegean Sea* decided to berth the ship. As it approached the coastline, however, the winds proved too strong, and the *Aegean Sea* was blown off course and onto the rocks that line the shoreline near the harbor entrance. Its double hull was breached, and 24 million gallons (109 million L) of lightweight crude oil, or "Brent blend," a mixture of oil from petroleum production facilities in the Ninian and Brent fields on the North

Greek oil tanker *Aegean Sea* aground in December 1992 near the harbor of La Coruña, Spain (© Daniel Beltra/Greenpeace)

Sea, was released onto the Galician coastline. After the grounding, almost all of the oil spilled from the tanker and into the water. High winds and the lightweight character of the oil allowed it to disperse quickly, and it eventually covered 125 miles (200 km) of coastline.

Although weather played a key role in creating the disaster, negligence by the ship's captain also contributed to the tragedy. Despite the poor weather conditions, the captain, in violation of several major maritime regulations, entered the shallow bay and approached the La Coruña docks. After grounding, in rough seas and poor visibility, the crew and captain were lifted off their foundering vessel by military helicopter and refused to provide any technical information about the ship, its cargo, or the condition of the vessel. They simply declined to speak about what had happened, fearing they would be held liable. In response, the Spanish authorities promptly arrested the entire ship's company. As a result, the captain immediately made the needed technical details available.

The oil slick created by the spill stretched more than 35 square miles (50 km<sup>2</sup>) and not only decimated the area's fishing and shellfish industries, which employed 20 percent of the residents, but

also shut down the tourist trade, just before a major pilgrimage and festival honoring a local saint. The Spanish government banned more than 800 fishermen from taking mollusks, barnacles, clams, cockles, and oysters for several years until testing indicated that the oil contamination had subsided to safe levels.

### CLEANUP OF THE SPILL

Spanish authorities tried to control and contain the spill, but the bad weather hampered conventional cleanup efforts using booms and skimmers. Instead, the slick was intentionally ignited in a technique known as in situ burning. Not widely used as an oil spill management technique, primarily because of concerns related to air emissions and the ability to control the fire once it is started, in situ burning can be effective when oil slicks are as thin as only 5/10 or 6/10 of an inch (2 or 3 mm). Once ignited, the oil burns the slick down to a thickness of a few tenths of an inch (1 to 2 mm). Below this thickness, the oil does not provide sufficient heat transfer ability to sustain combustion, and the underlying water dissipates most of the heat. In situ burning is used more frequently in remote arctic regions, where there are

fewer concerns over impacts to local air quality. Upon ignition, the slick became an inferno. Flames shot 164 feet (50 m) high into the air, and oil residues coated the Tower of Hercules, a 1,900-year-old Roman lighthouse that is still in active use some 1.6 miles (2.5 km) outside the city of La Coruña. The flames from the *Aegean Sea* burned much brighter, albeit for a much shorter time, than anything the Romans had envisioned as a beacon for this portion of the coastline.

As the fire raged in the harbor outside La Coruña, smoke and soot began to cover the town. Local authorities gave conflicting information to the citizenry, first assuring them that the foul odors and heavy fumes they smelled were not harmful. Then, to be safe, they suggested that residents should evacuate their harborside neighborhoods and seek shelter farther inland. The ability of local emergency response personnel to communicate effectively with residents was hampered by poorly coordinated informational bulletins and press releases and an unwillingness to involve local stakeholders (fishermen, environmentalists, etc.) in the planning and implementation of cleanup activities. Also playing a role in public skepticism was the memory of the 1976 spill of 100,000 tons (91,000 metric tons) of oil from the tanker *Urquiola*, which also washed up onto the Galician coast near La Coruña. It was more than 20 years before compensation claims for this incident were settled.

### LONG-TERM IMPACT AND LEGAL ACTION

Although the fires burned out after a few days, one year after the spill, the rocks along the La Coruña coastline were still coated with oil from the *Aegean Sea*. Biologists and environmental scientists predicted that ecological impacts, including reduced fishery yields, could linger for up to 10 years. Oil is still found today trapped below the rocky shoreline.

The International Oil Pollution Compensation (IOPC) Fund and the Spanish government established a claims office in La Coruña and began to process almost 1,000 claims by individuals, firms, and cooperatives for damage caused by the spill and subsequent fire. Upward of 320 million euros (\$200 million) was at stake, and most claimants also began legal proceedings. Eventually, the *Aegean Sea* captain, the vessel's owner, and the Spanish government were found jointly liable for the accident. Although claims related to loss of income from tourism, fishing, and fish farming were settled in a timely manner, those associated with shellfish harvesting were not resolved until 2002. As a result of the *Aegean Sea* disaster, the European Union adapted more

stringent procedures for ships entering harbors and approved new measures to protect traditional fishing areas and other ecologically sensitive zones.

**agriculture and pollution** In general, people do not want to consider that the most important activity for humankind's survival could be a grave source of pollution. By disrupting the naturally developed ecosystem of an area through the addition of water, fertilizers, pesticides, and nonnative plants, poorly conceived and implemented agricultural and horticultural practices not only are a major source of environmental damage, but also may be the largest source of pollution on the planet. It is debatable whether pollution from energy exceeds that of agriculture. The burgeoning human population on the planet, now almost 7 billion and growing, is consuming resources at such a breakneck pace that society has resorted to unsustainable practices in agriculture. Humans have even attempted the potentially risky practice of genetically engineering sources of food to increase the yields of such crops as corn and tomatoes. In 2005, a panel of experts convened at the United Nations (UN) Food and Agriculture Organization (FAO) recommended that "... any responsible deployment of Genetically Modified (GM) crops needs to comprise the whole technology development process, from the pre-release risk assessment, to biosafety considerations and post release monitoring." These recommendations are based on fears of

unanticipated side effects, but if serious efforts are not made to curtail population growth, there will be no choice but to continue to utilize genetic engineering to make crops more productive, nutritional, and disease- and pest-resistant.

There are many sources and effects of pollution in agriculture. There are sources, for example, that are specific to crops and those that are specific to livestock. Within each of these subdivisions, there are certain direct effects, such as pesticide and fertilizer use on crops, and indirect effects, such as eutrophication and dead zones from these practices. Some only result from catastrophic events such as flooding and earthquakes, others from long-term practices related to increasing the productivity of the land or a specific harvest. It is these cumulative effects from both sources that make agriculture a potentially serious pollution threat.

### **POLLUTION FROM GROWING CROPS**

Growing crops is, by far, the greatest source of pollution in agriculture. The U.S. Environmental Protection Agency (EPA) has estimated that agriculture-related pollution is the leading source of water

quality impacts to rivers and lakes, the third largest source of impairments to estuaries, and a major contributor to groundwater contamination and wetlands degradation. The environment is polluted primarily from farming practices, the use of pesticides, and the application of fertilizers. There are other sources of pollution, such as energy consumption in farming and in transportation of supplies to the farm and produce out to market. These additional sources of pollution are relatively minor when seen individually and even grouped together are small compared to the others.

There are several types of farming practices that are causing environmental problems now or in the past. They can be significant but typically are only noticed by officials and acted upon when they become extreme. Although there are many minor practices that contribute to pollution, the three major farming practices are deforestation, soil preparation, and use of water for irrigation and crop processing (cleaning, sorting, etc.).

### **Deforestation**

Trees are not helpful in growing most crops because they reduce sunlight and consequently photosyn-

**Crop dusting at Everglades Agricultural Area, a 700,000-acre (283,280-ha) tract of farmland created from the drainage of the northern Everglades, Florida (Florida Images/Alamy)**

**A diagram that shows how farming practices can cause pollution of soil, surface water, groundwater, and air through the use of inorganic fertilizers. The three processes creating pollution in addition to direct application to soil are evaporation to air, infiltration to groundwater, and runoff to surface water.**

thesis, and they commonly emit debris and growth inhibitors to reduce competing vegetation. As a result, trees are customarily removed prior to beginning an agricultural program. This has been the standard practice since farming began. Trees were cut down and the stumps pulled out to prepare fields for planting. Some of the wood may have been used for construction and heat for a home, but much of it was simply burned. In some cases, the area to be cleared was set ablaze and all of the vegetation just burned away. In either case, deforestation is not an environmentally friendly process.

There was always some pollution associated with deforestation. The burning of the wood and other vegetation produces particulate and other chemical pollutants, such as creosote, carbon dioxide, benzene, and polycyclic aromatic hydrocarbons (PAHs) among others. Trees are outstanding at stabilizing soil. When they are removed, there is necessarily some soil erosion that can silt up streams and other surface water bodies. It also increases mass movement of soil (e.g., landslides) that have their own set of related pollution events.

The current problems of concern with deforestation are greenhouse gases and global warming. By virtue of their size and rapid growth, there is a high

ratio of photosynthesis to ground space in a tree. Trees convert more carbon dioxide to oxygen than most other types of vegetation. Stripping large trees in favor of smaller and more widely spaced crop plants generally reduces the amount of photosynthesis, and, in many cases, the reduction is significant. Deforestation is indirectly adding more carbon dioxide to the atmosphere.

There is no place on Earth where this is more of a problem than in the tropical rain forests, particularly in Central and South America. They are continuously being bulldozed over and burned to make room for croplands at a breakneck pace. Roughly half of all tropical rain forests worldwide, or 1.85 million of 3.7 million acres (750,000 of 1.5 million ha), have been destroyed, and, at the current rate of cropland conversion, only 10 percent will remain by 2030. This practice is contributing to the carbon dioxide problem because, unlike at high latitudes, these trees and associated vegetation grow and photosynthesize throughout the year rather than only in growing seasons. It is estimated that the rain forests have historically produced 20 percent of the world's oxygen from photosynthesis. In addition, all of the nutrients for growth are contained in the vegetation, litter, and canopy. The soils beneath are deeply

weathered lateritic types with all of their nutrients long since stripped away by chemical weathering. Tropical soils must be continuously supplemented with fertilizers to support vegetation, and if they are abandoned, many decades to centuries are required to restore them to their original natural and productive state.

### Soil Preparation

Since the beginning of civilization, the practice of soil preparation involved plowing of the soil. This practice is and was done to soften the soil and to turn under and kill the native vegetation. The softened soil allows easier planting of seeds and easier penetration of the roots into the ground. Rapid penetration allows quicker growth of the plants to larger size, as the root size is commonly proportional to the plant size. Plowed soil also allows better use and drainage of water, which infiltrates the soil and is delivered to the root systems more quickly, with less lost to runoff.

But native vegetation serves many functions in protecting the soil. It holds moisture in, thereby preventing the soil from drying out. It also prevents the soil from eroding any further than the practice of deforestation has already caused. The result of ground preparation for the crops is and was wide, open bare soil at the mercy of the elements. Fortunately for us, normally the elements are kind and farmers can plant and harvest their fields without much problem. In some years, however, that is and was not the case.

In the South Central United States, there was a particularly hot and dry weather period beginning in 1926 and continuing to 1934 but not fully recovering to normal conditions until the end of the 1930s. The exposed soil dried out on the fields, and cover vegetation did not even take over during the off-seasons. Even the most fertile soil became a dry powder. When the winds came, they blew much of this powder into great clouds and storms of dust or particulate. It was for this reason that the term *dust bowl* was coined. When a dust storm struck, the particulate was so thick that there was no visibility. People put sheets over their doors and windows, but the dust got into everything and settled onto houses, on the ground, and into streams, up to several feet deep in some cases. It silted up streams and polluted the air. People suffered increased respiratory illness from inhaling the dust.

The dust bowl ended and new farming practices were introduced to curtail such events in the future. The dust bowl is a stark example of how agricultural practices can produce pollution problems. The change in conditions during the dust bowl was so

great that the government and residents alike agreed to change farming practices. The same problem has happened and is happening in many other places around the world, but in most cases it is more subtle and as a result is not acted upon as quickly or effectively as it should be.

### Water Usage

Crops need water in order to grow. Natural precipitation would be the most efficient and best source of this water, but nature is not reliable enough for our needs. Therefore, farmers must water their fields. In the early days, people simply planted near bodies of water, such as rivers, and hoped they would not flood. Otherwise, they would lose an entire year's crop. This was a devastating event. To avoid such catastrophes and because they quickly ran out of space, farmers began planting farther from rivers. As a result, they were forced to devise irrigation systems, which have grown ever more efficient and complicated over the years. If cropland is near a non-estuarine river or other surface water body, typically there will be a combination of surface water and well water used for irrigation. If the land is distant from a surface water source, irrigation is provided purely by well water.

The main pollution problems associated with water usage are desertification and degradation of the water source as a result of drawdown. The best example of desertification resulting from overuse of surface water for irrigation is the Aral Sea in Russia. Enhanced agricultural efforts in the region required excessive irrigation because the area is so dry. As a result, the Aral Sea began to shrink and soon lost one third of its area before agricultural activities subsided in the area. The newly exposed land is primarily a desert.

Overuse of water also can affect river systems. Although much water in a river is also typically used as drinking water, the agricultural component can be very high. Just as with the Colorado River, the primary effect is decrease in discharge caused by the reduced volume. The secondary effect is the degradation of water quality. The lower water level tends to draw more base flow from the water table into the river as it increases its effluence. Polluted groundwater may be drawn from greater distances to the river; runoff, which is of notoriously lower quality, makes up a larger percentage of the river water, and the shallower water in the river allows a higher degree of evaporation, thus increasing salinity. The same effects can occur in lakes and ponds.

The truly worrisome part of overuse of water is the effect on major aquifers. Some aquifers, the High Plains, or Ogallala, Aquifer of the midwest-

ern United States, for example, are primarily used for irrigation. The Ogallala is used 94 percent for irrigation, and the heavy draw from it has dropped the water table 100 feet (30 m) on average and up to 175 feet (54 m) in some areas. It has drastically altered the depth and dynamics of the streams and rivers in the area because base flow is reduced. It also tends to draw more water from areas that are somewhat saline as well as from the surface, and, consequently, the quality of the water has suffered as well. The water in the Ogallala is largely recharged from surface, but there are other aquifers that were formed during the last ice age, 13,000 years ago, and recharge has been very slow ever since. This water is being drained and not replaced. Eventually, these aquifers will no longer be able to irrigate the farmlands and a crisis may ensue.

### AGRICULTURAL CHEMICALS

Agricultural chemicals are those manufactured substances or cultivated organisms that are used to destroy, stupefy, repel, inhibit the feeding of, or prevent pests from attacking plants or other related products. These include agents that destroy a plant or modify its physiology, modify the effect of

another agricultural chemical product, or attract a pest for the purpose of destroying it. Typically, agricultural chemicals include herbicides, insecticides, and fungicides. Fertilizers are not considered agricultural chemical products. Some government regulatory agencies also classify plant growth regulators (hormones) and veterinary medicines as agricultural chemicals that require special registration and application controls.

The use of agricultural chemicals is one of the main reasons that farmers are able to feed more people with crops produced from the same amount of land. For example, China produces enough food for 21 percent of the world population on 9 percent of the world's cultivated land. This is possible only because 75 percent of crop nutrients are now supplied and managed by agricultural chemicals, particularly fertilizers. The use, and often overuse, of agricultural chemicals, however, can have severe ecological and environmental implications.

### Pesticides

Pesticides have been one of the greatest inventions of humankind and yet may cause the most problems as pollutants. Pesticides have eliminated many of the insects and other pests that reduce crop yield.

Erosion along Cane Creek, 1985, caused by an upstream channelization project © Karen Kasmauski/CORBIS

Honey bee (*Apis mellifera*) on white flower (Elemental Imaging, 2008; used under license from Shutterstock, Inc.)

The relationship of American farmers and pesticides has been described as a love affair. They have been used with wanton abandon to increase crop yield, and, as a result, they have turned the Midwest into the breadbasket of the world. They have allowed enough food to be produced to supply the burgeoning human population. They are truly one of the saviors of civilization.

The overuse of pesticides has negative aspects as well. The negative issues with pesticides are now well known as the result of the tireless efforts of environmental activists. Rachel Carson began her crusade against environmental pollutants, particularly against pesticides. Her 1962 book *Silent Spring* identified by name the most dangerous of pesticides, particularly dichlorodiphenyltrichloroethane (DDT). These efforts eventually resulted in the formation of the U.S. Environmental Protection Agency (EPA) and the banning of DDT and many other agricultural pesticides of the time. Other heavily regulated or completely banned pesticides include aldrin/dieldrin, carbofuran, chlordane, 1,2-dibrom, 3-chloropropane (DBCP), diazinon, endosulfan, endrin, hexachlorobenzene (HCB), hexachlorocyclohexane (HCH) or lindane, heptachlor, methyl parathion, pentachlorophenol (PCP), and toxaphene, among others.

The reason that all of these pesticides that took years to develop at great cost were banned was not their effect on pests but their collateral damage to people and the environment. One of the defining events that caused Rachel Carson to become involved in opposing the use of DDT was a bird kill in Massachusetts that resulted from indiscriminant application of DDT. Later, it was found that the Cal-

ifornia condor was becoming extinct because DDT in its body was causing its eggs to have such a thin shell that they broke before hatching. Even though it ultimately survived, through the late 1960s, the California condor was a battle cry for opponents of DDT. It was not only birds that were suffering from pesticides. The frog and amphibian kills from pesticides and destruction of habitat are even more impressive. Estimates are 122 species of amphibians have been lost since 1980 and that 32 percent of the remaining species are on the brink of extinction. In Central America, two thirds of the native frogs are extinct. These numbers are equivalent to the worst extinction events in the history of the planet.

Most people are generally not overly concerned with the losses of wild birds and frogs because they do not affect them directly. Another failing group that may be of a bit more concern are bees. The population of bees in North America has been steadily decreasing since the widespread use of pesticides began in the 1940s. This slow decrease abruptly changed to a precipitous drop in the 2000s. A new syndrome called colony collapse disorder (CCD) began to wipe out whole nests at a time in great numbers. Between 2006 and 2007, it is estimated, one third of the remaining bees died off. The cause of CCD is still under debate, and parasites and viruses have been the leading theorized agents. Pesticides have certainly taken their toll on bees because many of them are at least as toxic to bees as they are to the target insects. The pesticide imidacloprid has emerged as a likely contributor to the problem because it is relatively safe to humans and mammals but very toxic to insects. It is consequently used in higher quantities than perhaps it should be.

The loss of bees will not only decrease our supply of honey. Bees are the main pollinators for most of our fruits and vegetables. There are already problems for cranberries, blueberries, and apples from just the decreasing bee populations. Albert Einstein is credited with having said that if the bees became extinct, humans would follow within four years. Without them, the food supplies would dwindle until we starve to death.

Pesticides also get into the water supply from washing off fields during precipitation into the surface runoff. This runoff enters the surface water system in lakes and rivers that may be used for human consumption. Some pesticides are systemic, meaning they are taken into the plants through the roots and distributed throughout the plant. When the plant is harvested, the pesticide is included and cannot be removed. Pesticides are also blown into the atmosphere, where they can be carried great distances. Pesticide residues have been found in glacial ice in Greenland. All of

this exposure to persistent pesticides increases their level in the human body. In the 1970s, the levels of pesticides in human mother's milk were found to be dangerous. With all of the efforts to reduce ambient pesticides in foods and common items, levels of pesticides in human milk have been reduced to moderate levels. The long-term health effects of exposure to pesticides have yet to be determined.

### AGRICULTURAL NUTRIENTS

Fertilizers are nutrients needed to grow plentiful, useful plants. They can be divided into two basic categories: macronutrients (needed by plants in large quantities) and micronutrients (necessary in much smaller amounts). Macronutrients include nitrogen (N), phosphorus (P), and potassium (K), and some agricultural experts add sulfur (S) to the list. Nutrients required in small amounts (sometimes called trace elements or secondary nutrients) include boron (B), copper (Cu), iron (Fe), chlorine (Cl), manganese (Mn), molybdenum (Mo), and zinc (Zn). Fertilizers are the materials developed to deliver these macro- and micronutrients to the soil in a way that they can be utilized by plants. All of these nutrients are present in nature, but not in the quantities sufficient to satisfy the needs of the world's expanding urbanized population. According to 2007 statistics provided by the International Fertilizer Industry Association, the global fertilizer industry produces some 187 million tons (170 million metric tons) of fertilizers annually. There is no substitute for the nutrients absorbed by crops, and fertilizers are essential ingredients in a sustainable food supply.

#### Fertilizers

The other savior of humankind is agricultural fertilizer. In years past, natural fertilizers were used but were limited in their effectiveness. The recent and new chemical fertilizers that have been developed and tested in laboratories are extremely effective for growing crops with the highest yield in the shortest growing season possible. The output of plants allows farmers to produce more food, and, with more food, a larger human population can be maintained. The burgeoning population and enhanced lifestyle are largely the result of effective fertilizers.

The more the population increases, the more the demand there is on farmers to produce food. Consequently, farmers use even more fertilizers, to the point where they are at excess levels in the environment. These excess levels mainly affect surface water. A small part of the applied fertilizers are swept off fields in runoff after a rainstorm. If they migrate into a surface water system, they strongly

**A graph showing the increased use of fertilizer from 1960 to 2000—the drop in the 1990s reflects the decline and reorganization of the former Soviet Union.**

affect it. Nearly every pond and small lake in the United States is affected by excess nutrients such as the kind introduced by fertilizers. These excess nutrients cause eutrophication of the pond, which is a condition in which an initial algal and plant bloom results in massive oxygen-consuming bacterial growth to consume dead vegetation. The pond becomes hypoxic (oxygen deficient), and much of the native life dies.

Minimal efforts were made to battle eutrophication because ponds and small lakes are not major suppliers of food. In the 1960s, however, a major zone of eutrophication (oxygen deficiency) appeared in the Black Sea of the USSR as the result of runoff from overfertilized cropland. The zone was named a dead zone because virtually all of the fish and invertebrate life either died or quickly fled the area, leaving it devoid of life. Only minor notice was taken of the phenomenon because it was in the USSR and because the Black Sea is small and restricted. These dead zones began appearing in other places as well through the 1980s and 1990s and continuing today. They primarily appear where rivers empty into the seas or oceans in bodies of water with somewhat restricted circulation. The fertilizer is swept into runoff, and the rivers carry it to the sea, where it accumulates. For example, the Mississippi River drains the entire breadbasket of the United States, and, as a result, one of the largest dead zones in the world is in the Gulf of Mexico at the mouth of the Mississippi.

There are now more than 200 dead zones worldwide and most are associated with overuse of agricultural fertilizer. These growing areas are devoid of edible marine life and as such are severely reducing output. The zones appear in the most productive

**A graph showing the growth of human population from 1750 to 2000**

marine areas, such as the Gulf of Mexico, Chesapeake Bay, and coastal Oregon. They are reducing the marine food supply, and if dead zones are left unchecked, they may lead to a global food crisis.

### POLLUTION FROM LIVESTOCK

Aside from the inhumane treatment of livestock in order to meet the demands of burgeoning human population, there are certain sources of pollution to the environment and threats to public health. Many crops are grown for livestock, so pollution generated in the process is at least partly attributable to livestock. Direct pollution from livestock is largely caused by waste except in catastrophic events. With huge numbers of livestock come huge amounts of animal waste to deal with. At times, this waste has contact with the food supply and there are outbreaks of *Escherichia coli* and *Salmonella*, among other bacteria, that can spread across the nation, causing sickness and sometimes death. Considering the vast amount of produce generated, these outbreaks are relatively rare.

The main problem is the disposal of the waste. In smaller operations, runoff from piles of waste flows into streams and rivers, causing eutrophication. In bigger commercial operations, the waste is pumped into large lagoons. There is significant generation of methane during the breakdown of waste. Flatulence from cows also contributes to the methane production from these areas. In the United States, cattle emit about 6 million tons (5.5 million metric tons) of methane per year to the atmosphere, accounting for 20 percent of total methane emissions. Methane is 23 times as strong a greenhouse gas as carbon dioxide.

There also are natural catastrophic events that can be devastating to those operations that are at maximal

capacity for the number of livestock. Catastrophic events have always been very damaging to livestock. Domestic animals lose their native instincts when they are herded and corralled their whole life, especially when many generations pass. In catastrophic events, animals commonly need that instinct to survive. The eruption of the Laki volcano in Iceland in 1783 emitted huge amounts of fluorine gas, which settled on and poisoned fields. The livestock ate the poisoned grass, and hundreds of thousands of them died. The 1920 Gansu earthquake in China is reported to have killed 200,000 livestock. These animal carcasses must be disposed of by burning or burying them in a secure grave as quickly as human bodies are, or they will generate disease and pollute local water supplies. Outbreaks of diseases such as cholera and dysentery can be as devastating as the disaster itself.

One of the most colorful cases of a natural disaster overwhelming livestock operations was Hurricane Floyd in North Carolina. Eastern North Carolina became a center for hog production. This growth was especially quick in the 1990s, when it grew from 2 million hogs in 1990 to 10 million hogs by 1997, making it the second largest hog producer in the United States. The area is low-lying and wet with a large number of streams and rivers. The hog waste was pumped into huge lagoons, 300 feet (92 m) by 150 feet (46 m), and filled 10–15 feet (3–5 m) deep in waste, many of which were in flood plains of rivers. By 1999, there were more than 4,000 waste lagoons in the area. In August 1999, Hurricane Dennis inundated the hog farming area with rain and flooded many streams. Two weeks later, before it could recover, Hurricane Floyd struck the same area. The flooding killed approximately 30,000 hogs, 2 million chickens, and 735,000 turkeys. It also washed out 38 waste lagoons completely and caused another 250 to overflow. It is estimated that 250 million gallons (950 million L) of untreated pig waste was dumped into rivers along with a huge number of carcasses. The smell was absolutely overpowering and prevented people from drinking the water, which was tainted with disease.

**air pollutants and regulation** The basis of air pollution regulation in the United States is the Clean Air Act. Originally passed in 1955 and called the Air Pollution Control Act (APCA), this was the first federal legislative action that addressed air pollution on a nationwide level. The 1955 APCA was directed to alert the nation to the problem of air pollution and allocate funds to study and define the problem. Eight years later, Congress took the next step and passed the Clean Air Act of 1963. This act set the first emission standards, or the amount of pollutants that was allowed to be discharged from a stationary source, such as a smokestack or chimney. Amendments to strengthen the act were passed in 1965, 1966, 1967, and 1969 and fixed limits on pollution from automotive vehicles, instituted compliance deadlines and schedules, expanded state and regional air quality control programs, and funded research on low-emission fuels.

Even with the regulations, improvements in air quality were moving too slowly. In 1970, the Clean Air Act was significantly strengthened through the

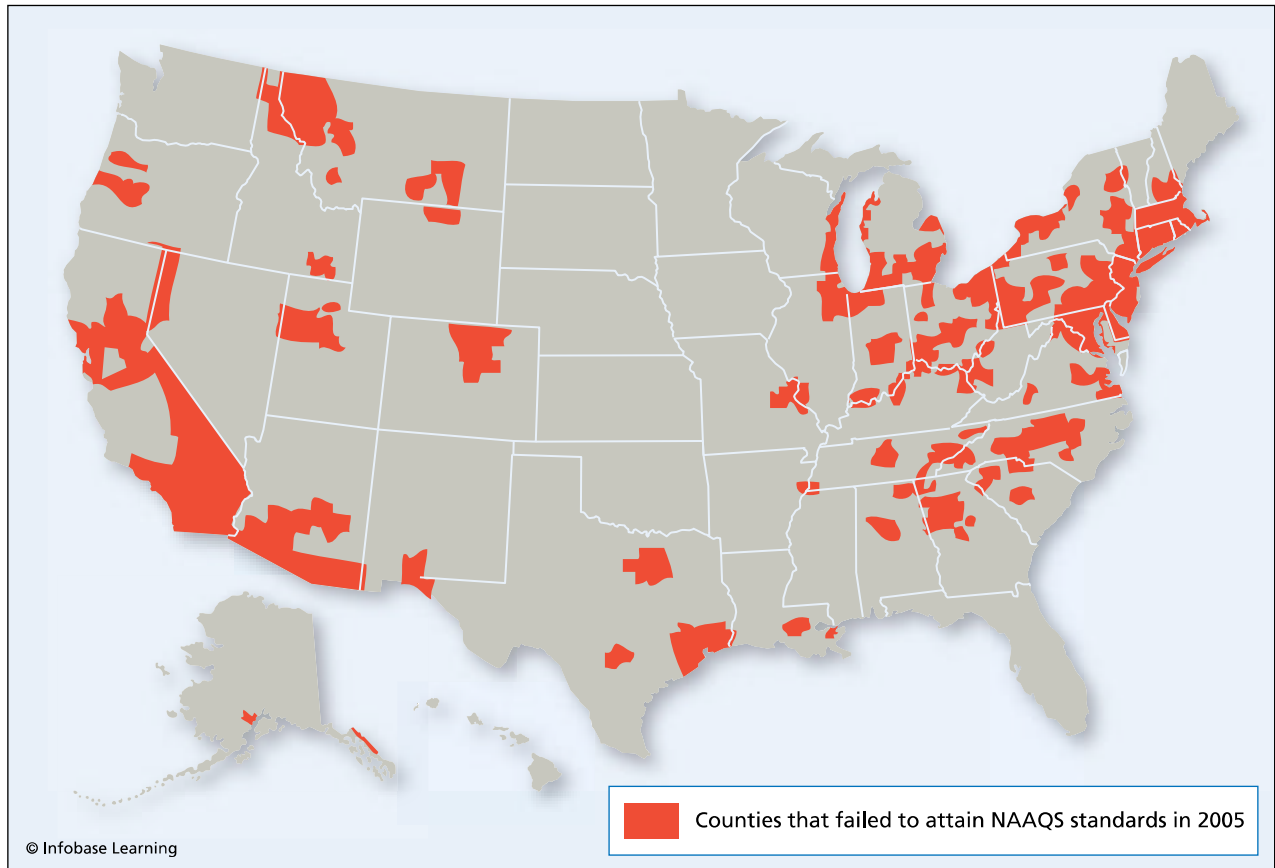

passage of a major set of amendments that created very demanding new emission standards for both stationary and mobile sources. The 1970 amendments also allowed enforcement and inspection programs to be conducted at the state level and increased funding related to air pollution control research.

Over the next 20 years, industrial America struggled both technologically and financially with the ambitious goals and deadlines of the 1970 Air Pollution Control Act. By 1990, the federal government decided the country was ready for the next step in improving air quality. The 1990 Clean Air Act Amendments included tougher air-quality standards and motor vehicle emissions, mandated the study and eventual use of alternative (nonhydrocarbon) fuels, and required the elimination of certain types of toxic air pollutants, control of acid rain, and phaseout of chemicals that were causing reductions in stratospheric ozone levels.

For pollutants where the scientific evidence was sufficient to establish a genuine concern that they might be harmful to public health or environment, the 1990 Clean Air Act required the U.S. Environmental Protection Agency (EPA) to establish National Ambient Air Quality Standards (NAAQS). This was done for six pollutants called criteria pollutants. The Clean Air Act as amended in 1990 (often abbreviated CAA) required EPA to develop regulations to monitor and control the discharge into the atmosphere of pollutants that pose unacceptable health or environmental risks. The CAA created two types of NAAQS for the criteria pollutants considered harmful to public health and the environment:

1. *primary standards*—designed to protect public health, including "sensitive" populations: asthmatics, children, and the elderly
2. *secondary standards*—created for the protection of air clarity (reduction of haze), animals, crops, vegetation, and buildings

The standards are stated in maximal concentrations allowed on an hourly, quarterly (three-month), or annual (yearly) average basis as measured in parts per million (ppm) by volume, milligrams per cubic meter of air (mg/m<sup>3</sup>), and micrograms per cubic meter of air (mcg/m<sup>3</sup>). For each of these pollutants a mandatory, federally enforceable maximal concentration has been set that any stationary source may not exceed. Primary standards are those limits designed to protect public health directly. This includes particularly sensitive populations, such as people who have chronic lung disease (asthma), children, and elderly

**A map of the United States showing areas that failed to meet the EPA National Ambient Air Quality Standards in 2005**

adults. Secondary standards are those that seek to control pollutant discharges at concentrations that may decrease visibility or damage animals, crops, vegetation, or buildings. Areas where concentrations of one or more of these criteria pollutants exceed NAAQS are designated as nonattainment areas, and local governments must develop plans to reduce or control pollution levels to make the area in compliance with NAAQS.

Not included as part of the NAAQS is a class of compounds called toxic air pollutants, also called Hazardous Air Pollutants, or HAPs. These are substances that, when discharged into the atmosphere, have been linked to severe health effects including cancer or birth defects and/or environmental damage including destruction of vegetation or degradation of soil and water quality. Compounds such as benzene, present in gasoline; perchloroethylene from dry cleaning; and methylene chloride, a solvent and paint stripper, are examples of common HAPs along with dioxin, asbestos, and metals such as cadmium, mercury, chromium, and lead.

The 1990 Clean Air Act lists 188 HAPs, and EPA has developed a two-phased approach to their regula-

tion. The first phase is a technology-based method, which consists of the development of Maximum Achievable Control Technology, or MACT, standards. These standards require a business or company discharging a HAP into the atmosphere to meet emission limits based on levels already being achieved by similar sources elsewhere in the country. In the next phase, the EPA applied a risk-based approach. This was done to identify whether technology-based emission limits were sufficient to manage the health and environmental risks associated with HAP emissions. Once this was completed, the EPA developed more stringent standards for certain HAPs to control any remaining or residual health/environmental risks.

**air pollution** Any input of chemical, aerosol, or particulate that is not found as a significant component of everyday air is considered to be air pollution. This definition allows for vast numbers of pollutant types and chemicals. At any time and anywhere, there are bound to be vast amounts of contaminants in the air, but it is rare for them to reach significant and especially unhealthy concentrations. Certainly, since the beginning of the Industrial Revolution, the amounts and varieties of air pollutants have increased exponentially, at least until 1970, when the Clean Air Act was signed into law. It was once assumed that the oceans would modulate most of the anthropogenic additions to the atmosphere, but that theory eventually was proven wrong when significant amounts of anthropogenic air pollutants found in glacial ice and atmospheric components of gases such as carbon dioxide showed dramatic increases (e.g., the “hockey stick” graph of Al Gore).

The Clean Air Act identified six “criteria” air pollutants, namely, carbon monoxide, lead, nitrogen dioxide, ozone, particulate matter, and sulfur dioxide, as those in most dire need of reduction. The most widespread danger of these to human health is ground-level ozone, although all can cause adverse health effects. Part of the chemical makeup of each of these “criteria pollutants” has natural sources (forest fires, volcanoes, etc.) and part is anthropogenic; some sources (natural or anthropogenic) contribute more than others. Since 1970, the concentrations of most “criteria pollutants” have diminished in the air across the United States to varying degrees. In 1990, the U.S. Congress revised and expanded the Clean Air Act, establishing stricter standards for criteria pollutants. As a result, numerous cities or urban regions were unable to meet these new, stricter standards and are now being faced with an obligation to improve their air quality further. Many have never been able to meet the 1990 standards consistently. There were also several amendments that placed an emphasis on more cost-effective methods to reduce air pollution. In 2007, carbon dioxide was also declared an air pollutant even though it is a natural by-product of respiration of numerous organisms. The reason for

its change of status is that it is the main greenhouse gas implicated in global warming, and there is a tremendous amount of anthropogenic carbon dioxide being emitted to the atmosphere.

The quality of air in the United States has greatly improved since the Clean Air Act was enacted in 1970. Europe, Japan, and several other industrialized nations also have cleaner air as the result of similar governmental legislation. Even with the efforts of these nations, however, global air quality has continued to decline, with no indication of a reversal in the near future. China now has 16 of the 20 most polluted cities in the world, and several cities in India have also become severely polluted. Until these huge countries with massive populations, as well as the numerous smaller, less-developed countries, begin to curtail their pollutant discharges to the atmosphere, conditions will not improve.

Air pollution can be subdivided in many ways by source, components, and mode of formation. The first major division, however, is whether it is primary or secondary.

**Graphs showing the concentrations of the six criteria air pollutants in the United States from 1940 to 2000**

## AIR POLLUTION IN NATIONAL PARKS

The first national park in the United States was Yellowstone, established, in 1872 by an act of Congress. Tucked into the northwest corner of Wyoming, Yellowstone National Park encompasses 3,500 square miles (9,065 km<sup>2</sup>) of mountains, streams, and forests that is home to a wide variety of charismatic megafauna: grizzly bears, wolves, bison, and elk. Within the park are Old Faithful and a collection of other extraordinary geysers, hot springs, geothermal vents, and special geological features including the Grand Canyon of the Yellowstone, a deep gorge cut into bedrock by the Yellowstone River.

Since the creation of the National Park Service in 1916, the United States has dedicated 80 million acres (324 million ha) of unique natural resources and historic places, which includes almost 400 sites ranging from untouched wild and scenic rivers to handicap-accessible urban parklands and well-developed shorelines. They represent the “crown jewels” of the nation, open to all and held forever in trust for the public’s enjoyment. The parks are divided into several categories.

Unfortunately, the parklands do not exist in either a cultural or a geographic vacuum, and with almost 300 million people visiting the nation’s battlefields, monuments, and scenic areas every year, they are susceptible to many of the ills inherent in modern society: crime, overcrowding, and pollution, particularly air pollution. Many, if not most, of the national parks are still some of the most environmentally pristine places in the country, but air pollution from surrounding, more developed and urbanized areas can intrude on

the public’s expectation of clean air. Air quality in the national parks first surfaced as an issue in the 1950s, and since then the National Park Service has been struggling to monitor and control the following three basic types of air pollution: haze, ozone, and acid rain.

### HAZE

Caused by fine particulate suspended in the air, haze interferes with local visibility and detracts from the panoramic vistas and scenic wonders of many national parks. The absorption of light, also called light extinction, not only reduces visibility, but also decreases or bleaches out the sharpness and vividness of natural colors. The white haze present almost year-round in Great Smoky Mountains National Park, Tennessee, reduces the average visibility to 24 miles (39 km), whereas the expected natural (unpolluted) visibility should be 93 miles (150 km). The decrease is due to the light scattering and adsorption effects of very small (micrometer) sized particles and gases (aerosols), primarily fossil fuel combustion by-products such as sulfur dioxide (SO<sub>2</sub>) and nitrogen oxides (NO<sub>x</sub>). These particles are blown into the park by eastern coal-fired power plants that lack adequate air pollution control devices.

### OZONE

Ground-level ozone is produced by the chemical reaction of nitrous oxides (generated by the burning of

U.S. NATIONAL PARKS			
Type	No.	Description	Example
International historic site	1	Sites with special, multinational significance or status.	Saint Croix Island International Historic Site, Massachusetts. Halfway between the equator and the North Pole, this site commemorates the attempted French settlement of North America.
National battlefields, memorials, and associated military parks	52	Sites that commemorate or honor a historic person or event.	Flight 93 National Memorial commemorates the passengers and crew of Flight 93, who, on September 11, 2001, gave their lives to thwart a planned attack on the nation's capital.
National historic site	78	A place that is associated with a person or subject of historical interest.	Edison National Historic Site, New Jersey. The research and development laboratory as well as residence of the famous inventor
National historical parks	42	Applies to multistructures or parcels that incorporate more than a single property or building.	Boston National Historical Park, Massachusetts. Associated with the American Revolution. Sites include Bunker Hill, Dorchester Heights, Old North Church, and Paul Revere House.
National lakeshores and seashores	14	Shoreline areas adjacent to the Great Lakes and inland water bodies. Some have facilities for use by the general public, while others are relatively undeveloped.	Indiana Dunes National Lakeshore. 25 miles of shorefront along southern Lake Michigan. This area contains beaches, extensive sand dune systems, wetlands, and historic sites.
National monuments	74	Landmarks, structures, and other objects of historic or scientific interest situated on lands owned or controlled by the government.	Canyon de Chelly National Monument, New Mexico. Features ruins of prehistoric Native peoples constructed around 1300. Located at the base of cliffs and tucked into canyon wall caves.
National parks	58	Large, natural areas containing a variety of special characteristics, including significant historic features. Consumptive activities (hunting, mining, etc.) are not permitted.	Glacier National Park, Montana. Unspoiled mountainous terrain hosting glaciers, lakes, and streams, as well as many types of unique flora and fauna.
National parkways	4	A roadway and adjoining parallel parkland intended for scenic motoring. These often connect cultural or historic sites.	Natchez Trace Parkway. Road that generally follows a Native American trail (trace) between Nashville, Tennessee, and Natchez, Mississippi
National reserves and preserves	20	Areas with features similar to those of national parks, but where public hunting, trapping, oil/gas exploration, and extraction are allowed.	Yukon–Charley Rivers National Preserve. Established on the Canadian border in central Alaska. This 115-square-mile (398-km <sup>2</sup> ) area encompasses the 1,800-mile (2,897-km) Yukon River and the Charley River basin.

(continues)

<b>U.S. NATIONAL PARKS</b> <i>(continued)</i>			
<b>Type</b>	<b>No.</b>	<b>Description</b>	<b>Example</b>
National recreation areas	18	Urban parklands combining open spaces with the preservation of significant historic resources. Founded in areas that can provide outdoor recreation for large numbers of people.	Santa Monica Mountains National Recreation Area, with 600 miles (966 km) of hiking trails and a 55-mile (89-km) scenic drive across the Santa Monica Mountains, near Los Angeles.
National rivers, including wild and scenic rivers	15	Rivers that possess outstandingly remarkable scenic, recreational, geologic, fish and wildlife, historic, cultural, or other similar values. They and their immediate surroundings are preserved in free-flowing, undeveloped condition.	Rio Grande Wild and Scenic River, Texas. A 190-mile (306-km) stretch strip of the Rio Grande (American side) flowing through the Chihuahuan Desert.
National scenic trails	3	A system of linear parklands (more than 3,600 miles or 5,800 km) managed jointly by the NPS and nongovernmental agencies.	Appalachian National Scenic Trail. A 2,100-mile (3,380-km) trail from Maine to Georgia, passing through 14 states.
National seashores	10	Designated areas on the Atlantic, Gulf, and Pacific coasts. Facilities range from handicap-accessible to largely undeveloped. Hunting and fishing may be permitted.	Assateague Island National Seashore, Maryland. A 37-mile (60-km) barrier island that is host to wild horses and more than 300 species of birds.
Other parks (other)	11	Unique or other special sites not otherwise classified.	White House (President's Park), Washington, D.C. Since the early 1800s, serves as the residence and office of the U.S. president.
<b>TOTAL:</b>	<b>400</b>		

*(continued from page 18)*

fossil fuels) with volatile organic compounds (from industrial sources and automotive exhaust) in the presence of sunlight. Ozone also is formed by the release of isoprene, a naturally occurring volatile organic compound released by plants. Ozone contributes to haze and damages vegetation. It penetrates the plants' stomatas during photosynthesis and causes cellular damage. Symptoms of foliar (leaf) overexposure to ozone include changes in plant coloring or pigmentation, premature aging and senescence (reduction in cell division rates), chlorosis (insufficient production of chlorophyll), and necrosis (unintentional cell death).

Ozone-induced foliar injury has been reported within the 35,000-acre (14,164-hectare) Acadia National Park in Maine. Comprising a cluster of islands off the Maine coast, Acadia was established in a wide transition zone between eastern deciduous and

northern coniferous forests. Although there are few major industrial pollution sources within Maine, Acadia is downwind of large urban areas to the south and west. Consequently, high concentrations of air pollutants are blown into the park from these areas. Ozone monitoring at Acadia began in 1982, and since then data indicate numerous violations of the one-hour and eight-hour health-based primary National Ambient Air Quality Standard (NAAQS) for ozone.

#### **ACID RAIN**

When sulfur and nitrogen compounds (released during the burning of coal) combine with water vapor in the atmosphere, they form droplets of sulfuric and nitric acids. As these droplets are washed out as rain, snow, or fog, they increase the acidity (reduce the pH) of streams, lakes, and soil. Acidification of the national parklands presents particular problems because so

many of them are unique, ecologically sensitive areas that are not able to adjust to these types of outside assaults on their environmental integrity. In the mountainous areas of the Appalachian National Scenic Trail, for example, the soil cover is relatively thin and has a limited ability to release enough basic minerals to buffer acidic rains. As soil pH decreases, calcium uptake by plants is reduced, and aluminum, which is toxic to plants, becomes bioavailable. Acid rain can also damage historic monuments, markers, and statuary such as those at Gettysburg National Military Park, among others.

Fortunately, air quality in most national parks is improving. In 1977, the U.S. Congress recognized the need to provide special protection for national parks from air pollution and, as part of the Clean Air Act, designated most national parks, wilderness areas, international parks, and national wildlife refuges as class I attainment zones. This special designation gives state and federal regulatory agencies special authority to prevent future and remedy existing visibility problems that are caused by anthropogenic pollution. Efforts to improve air quality in the national parks have had a mixed record of success because of uneven or inconsistent governmental funding and enforcement priorities.

The Air Resources Division of the National Park Service (NPS) operates a system of air monitoring stations in 70 national parks across the country, many for more than 20 years. This system is designed to measure levels of air pollutants and, at some stations, collect important meteorological information. These data are needed in order to assess long-term trends that may impact parkland ecologies. The informa-

tion collected also helps determine compliance with National Ambient Air Quality Standards (NAAQS) and evaluates the effectiveness of local and regional air pollution control policies and initiatives.

The monitoring programs collect and analyze air samples for three types of pollutants: visibility reducers (fine and coarse particulate [PM<sub>2.5</sub> and PM<sub>10</sub>] sulfate, nitrate, organic and elemental carbon), ozone and other gases, and atmospheric deposition (sulfate, nitrate, ammonium, cations [metals], mercury in precipitation, sulfur dioxide, sulfate, nitric acid, and nitrate). By providing these monitoring data to federal and state regulatory agencies that use them in policy development and enforcement actions, as well as aggressively developing and implementing air pollution control programs within park boundaries, the National Park Service was well on the way to meeting its goal of stable or improved air quality in 70 percent of its monitored parks by 2008. Between 1995 and 2009, 30 reporting parks showed stable or improving visibility on both the clear and hazy days, and 22 of 29 parks showed stable or improving trends in sulfate, nitrate, and ammonium concentrations. Of the 32 park units that monitor ozone, 20 (63 percent) reported stable or improving air quality trends. Overall, 68 percent of parks where air quality monitoring is taking place had stable or improved air quality.

The value of the monitoring program can be demonstrated in the northwestern United States, where a study of regional haze linked visibility-reducing sulfates at Mount Rainier to the Centrailia coal-fired power plant in Washington. The Centrailia plant

#### AIR POLLUTION CONTROL PROGRAMS AT NATIONAL PARKS

Mount Rainier National Park, Washington, White River maintenance building	Installation of a photovoltaic system to provide solar electricity (47 kW) for the building and associated maintenance operations. The NPS has installed more than 700 photovoltaic systems in its parks, monuments, and other properties.
Zion National Park, Utah, mass transit bus system	Natural gas-fired buses reduced traffic congestion in the park and air pollution associated with automobiles recreational vehicles (RVs), and diesel buses.
Joshua Tree National Park Cottonwood Complex, California	Installation of a hybrid photovoltaic and propane-fired electrical system that eliminated the need to burn 16,000 gallons (60,567 L) of heating oil annually.
Fire management, all facilities	Development of new control burn and fire management techniques/policies, in cooperation with local regulatory authorities, to minimize smoke and haze from these activities.

(continued)

generates approximately 1,340 megawatts, enough electricity to light up a city the size of Seattle. After a year of tough negotiations with plant operators, the NPS, in association with federal and state regulatory agencies, reached an agreement in which the plant upgraded its air pollution control equipment and reduced sulfate emissions from almost 70,000 tons per year (63,503 metric tons per year) to 10,000 tons per year (9,072 metric tons per year). Since then, visibility at Mount Rainier and in other parks of the Pacific Northwest has been improving significantly.

The National Park Service also funds and participates in many short-term studies and monitoring programs designed to gather data on individual parks to address specific questions such as identification of potential air pollution sources or assessment of ecological risks from designated air pollutants. The National Park Service, however, has no authority to enforce air pollution regulations outside the parks or monuments. Although it works closely with EPA and many state environmental agencies and regularly testifies before the relevant congressional committees that develop air pollution policy for the United States, it depends largely on the funding and enforcement priorities of other parts of the government, and the

pressure brought to bear by park users who want to enjoy clean, fresh air during visits.

### PRIMARY AIR POLLUTANTS

Primary air pollution means that the pollutants in the air have been released directly from their source, without having undergone any chemical reactions of another pollutant to attain their current state. All pollutants from natural sources are primary. The "criteria pollutants" can arise from primary sources, with the exception of low-altitude ozone, which is almost entirely anthropogenic in origin. Particulates are commonly primary, although many are not. Lead is always primary, and sulfur dioxide is mostly primary. Oxides of nitrogen are mixed. Carbon dioxide is overwhelmingly primary, but not completely.

London smog, named because it is so common in London, United Kingdom, is typical of cooler areas that have occurrences of heavy cloud cover or extensive fog (condensed water vapor). It has the appearance of brownish smoke, and smoke is typically a major component of smog (smoke + fog = smog). One of the worst air pollution disasters ever occurred in London in 1952 as a result of primary air pollution. One of the worst air pollution disasters in the United States occurred in Donora, Pennsylvania, and it was also dominantly primary air pollution.

### SECONDARY AIR POLLUTANTS

Secondary air pollutants are those produced from chemical reactions among primary or secondary air pollutants in the atmosphere. The reactions are primarily photochemical, meaning they are driven by strong sunlight. Secondary pollutants are more common in summer, when the rays of the Sun are more direct and the temperature is higher. The most common secondary air pollutant is ground-level ozone. It is produced by a photochemical reaction between volatile organic compounds (VOCs) and oxides of nitrogen. There are many other dissociation reactions requiring strong sunlight that can produce dangerous pollutants. Some photochemical reactions produce free radical ions that actually degrade and reduce dangerous air pollutants. There are secondary reactions that do not require strong sunlight, such as the reaction of sulfur dioxide to sulfuric acid. Instead, they involve reaction with moisture.

Smog that is composed primarily of secondary air pollutants is called photochemical, or Los Angeles, smog because it is so common there. In fact, most of the air pollution in the Southern California cities, as well as Denver, Colorado, is rich in secondary air

Airborne-deposited soot (particulate) accumulates on museum sculpture in London (Heather L. Jones; used under license from Shutterstock)

pollutants. Even though Denver is typically not as hot as Los Angeles, the stagnation of air and strong unimpeded sunlight are ideal for producing secondary air pollutants.

### NATURAL SOURCES

Although air pollution is typically thought of as dark clouds puffing out of a smokestack or an exhaust pipe, much air pollution has natural sources. Although some natural sources of pollution can be exacerbated by human activity, and some can be greatly altered by it, others continue to be unaffected by humans and will be present long after humans are gone. Although there are numerous sources of natural pollutants, from windblown salt spray to methane releases from the ocean floor, this section will consider only a few, namely, windblown dust, fires, volcanoes, biological pollutants, and crossover pollutants

### Dust Storms

Perhaps the simplest type of air pollution is wind-blown particulate. Strong winds passing over open sand or soil can lift tons of fine material into the air

and carry it aloft before depositing it. This suspended material constitutes dust storms and sandstorms, which are common in arid regions. This dust can be carried great distances across areas that produce no particulate. For example, dust lifted from the Sahara in northern Africa can be found as a component of the air pollution particulate in the Caribbean and even into the southernmost United States at times. The dust settles in areas where the wind is gentler or rises. The deposits formed by dust are called loess and can be quite extensive, especially in China.

Windblown continental dust is primarily made of very fine quartz from deserts, but it can also contain many other components, including iron, organic material, calcium carbonate, and even bacteria and other microorganisms. The dust provides nucleation sites for precipitation once it is out of the arid area. Large input of dust in the oceans can affect nutrient cycling and productivity. Inhalation of dust can also cause significant health problems.

Windblown dust is a natural process that would happen with or without the help of humans. Human activity, however, typically exacerbates the situation. The best example of human activity's increasing particulate is the dust bowl of the Midwest in the

Natural air pollution in the form of particulate and smoke is produced by a forest fire (Samuel Acosta; used under license from Shutterstock)

1930s. Poor farming techniques and a particularly dry period caused topsoil to dry out and be subject to wind erosion. Huge black clouds of dust produced darkness during daylight hours in many towns. Overgrazing of areas marginal to deserts removes the vegetation that holds the soil together and allows it to be eroded by wind. Overuse of water for irrigation dries out lakes. The case of desertification around the rapidly drying Aral Sea in the former Soviet Union is the prime example.

### Wildfires

It is questionable whether woodland fires can be considered natural, since so many are started by humans, but certainly, many others are caused by lightning in dry conditions. Fires produce an enormous amount of particulate, both fine and coarse. This is by far the largest component of air pollution from fires and the greatest health hazard. The visual density of the smoke shows the level of particulate, and it can literally turn the sky black and cover the Sun during daylight for many miles around the fire. Particulate can persist for tens to hundreds of miles (kilometers) away from the fire, depending upon its size and intensity as well as wind conditions. Other air pollution components depend upon the conditions of the fire. Typical chemicals released are carbon monoxide, carbon dioxide, oxides of nitrogen, and organic compounds. The organic compounds can be quite variable depending on the type of trees. Polycyclic aromatic hydrocarbons (PAHs) are emitted from all fires, but creosote is much more common from pine forests. Other compounds may include methylethyl ketone (MEK), benzene, toluene, and metals.

### Volcanoes

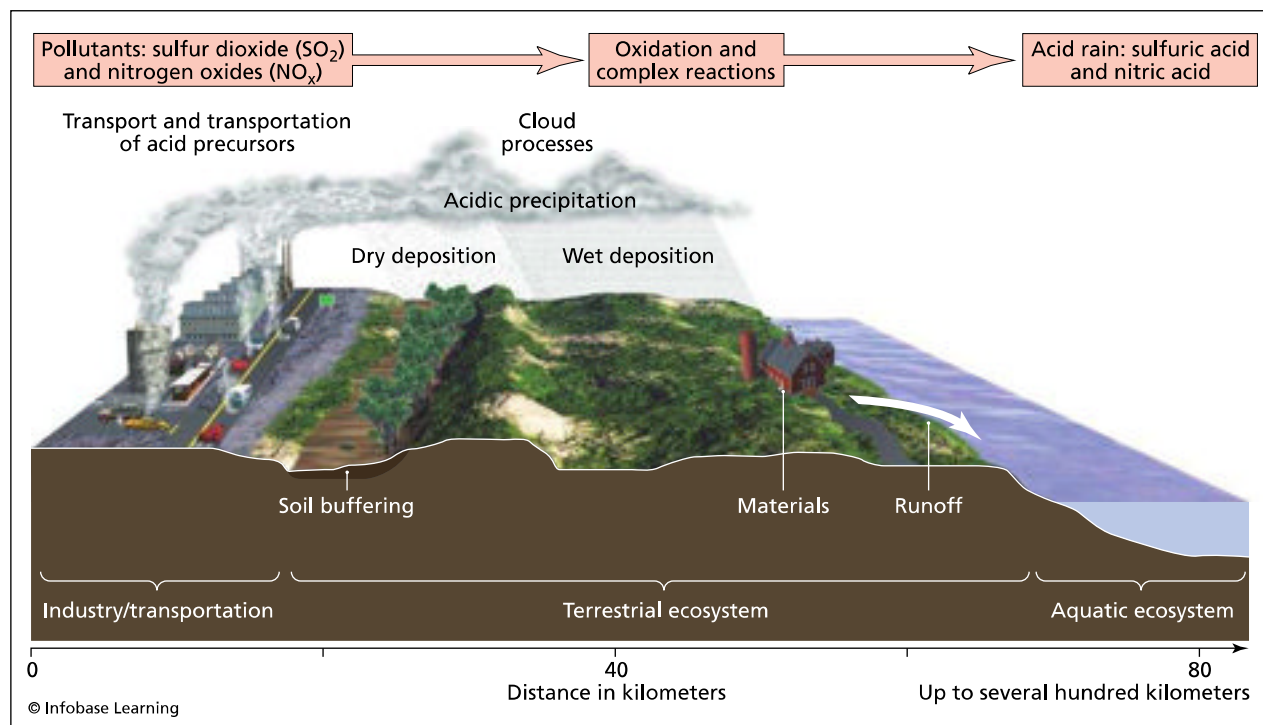

Although they are relatively rare, large volcanic eruptions have the capacity to put more air pollution in the atmosphere in a shorter time than any other source. As in wildfires, the main pollutant is particulate. This particulate in a volcano is pulverized rock and volcanic glass shards in the form of ash. The eruption column from a volcano can extend 45,000 feet (13,846 m) into the atmosphere. The ash not only covers the ground for many hundreds of miles (kilometers) downwind of the volcano, but may also circulate in the higher parts of the atmosphere for years. Although typical small eruptions like that of Mount Saint Helens in 1980 emit  $0.24 \text{ mi}^3$  ( $1 \text{ km}^3$ ) of ejecta (solid material), there have been larger eruptions, such as Tambora in Indonesia in 1815, that produced more than 36 cubic miles ( $150 \text{ km}^3$ ) of ejecta. So much fine ash filled the upper troposphere that it reflected a significant portion of the incident

Unless properly managed, cruise ships can be major sources of ocean pollution. (© Ron Watts/CORBIS)

sunlight back into space. As a result, 1815 is referred to as the “year without a summer,” because it was cold enough to have snow on the ground in June in New England. There was a severe worldwide famine from this event. Even more ominous is the fact that the Tambora eruption was not relatively significant on the Earth history scale. The volcano Toba in Indonesia erupted 74,000 years ago with 700 cubic miles ( $2,800 \text{ km}^3$ ) of ejecta. The climatic repercussions of that eruption must have been incredible.

Volcanoes also emit a significant amount of gas, both during the eruptions and between them. The most abundant gas is sulfur dioxide, which can produce acid precipitation nearby. Hawaii has acid rain problems from nearby volcanoes. Other gases include carbon dioxide, methane, water, and very minor amounts of many other compounds, such as fluorine, chlorine, methyl ethyl ketone (MEK), argon, boron and lithium compounds, benzene, and a huge number of metals. The gases are in such low quantity relative to the ash that they are usually overlooked. The best example of a problem with one of these minor gases occurred in 1783, when the

**A diagram showing generation of air pollutants from industrial and transportation sources, gravitational fallout (dry deposition) and precipitation washout (wet deposition) of acidic components (sulfuric and nitric acid), and transportation of acid into surface water bodies**

Laki eruption in Iceland produced so much fluorine gas that it poisoned hundreds of thousands of livestock and killed 25 percent of the human population on the island.

### ANTHROPOGENIC POLLUTANTS

Pollutants produced by human activity are numerous and diverse. There are a vast array of industrial organic compounds largely used as solvents, plastics, and chemical intermediaries and numerous heavy metals and heavy metal compounds that are mining related and industrial. This section reviews some of the sources of these chemicals, namely, the petrochemical industry, pesticides, transportation, and incineration.

#### Petrochemicals

When crude oil is removed from the ground, it is a mixture of a large number of chemicals with numerous properties. To separate these compounds for use in the various applications, the oil must be processed in a refinery. The main component of a refinery is a distillation tower in which the oil is heated and vaporized. The different densities of chemicals are condensed and removed as a function of height, the lighter compounds rising higher and the heavier

compounds remaining at the bottom (jet fuel at the top, tar at the bottom). This process produces the primary petrochemicals, which then are reacted with other chemicals using catalysts. Many of the distillates are piped to nearby chemical plants, where the petrochemicals are reacted to form still other industrial chemicals.

The easiest way to see the air pollution that is emitted from a refinery is at night when the gas is flared off in a giant flame. But the processes behind this flaring are much more complicated. Virtually all of the chemicals produced in a refinery are volatile organic compounds (VOCs), which are classified on the basis of their ready ability to evaporate. Anytime these chemicals are exposed to air, whether contained or in an accidental spill, fumes are released to the atmosphere.

#### Pesticides

Pesticides primarily enter the air through spraying. Many agricultural applications of pesticide use aerial spraying or crop dusting. Depending upon weather conditions, most of the pesticide settles onto the crops, but a significant amount can evaporate into the air or be blown away. The overspray not only affects areas adjacent to the application, but also can be carried great distances depending upon the

persistence of the compound. The residues of a number of pesticides have been found in glacial ice in the arctic, showing that these airborne pesticides can essentially circle the Earth. The residues in remote areas are in very low concentrations, but near the place of application, they can be quite large. They are removed from the air by direct gravitational settling, or “fall out”; attachment to particulate and settling; washout by precipitation; and chemical reaction with other airborne chemicals, particularly in the presence of strong sunlight. The dominant mode of removal depends upon the pesticide.

More recently, there have been less spraying and more seed application. Many of the pesticides are now systemic and are circulated throughout the vascular system of the plant. This protects the entire plant from attack by insects and fungus and constrains pesticide air pollution. The adverse effects on organisms that consume the plants may be enhanced, since the pesticides cannot be removed by washing.

### Transportation

The U.S. Environmental Protection Agency estimates that internal and external combustion engines associated with transportation are the single leading cause of urban air pollution. The burning of petroleum products generates numerous air pollutants, including particulate, carbon monoxide, anthropogenic carbon dioxide, oxides of nitrogen, sulfur dioxide, polycyclic aromatic hydrocarbons (PAHs), and other partially burned hydrocarbons. Previously, lead was also released into the atmosphere by transportation sources, but it has been banned since the 1970s. These primary air pollutants also react to produce secondary pollutants, especially ozone and acid precipitation. The combination of primary and secondary pollutants combine to make urban areas the most high-risk places in the world for respiratory health.

Advances in transportation technology have steadily improved the air quality of urban areas over the past three decades. Catalytic converters, unleaded and oxygenated fuels, and other air pollution devices reduce tailpipe emission of pollutants for most conventional engines and hybrid engines; pressurized natural gas (PNG) and fuel cells reduce the total amount of emissions including secondary pollutants. Improved public transportation and use of trains rather than trucks for freight hauling could greatly improve the air quality, but most areas do not have such systems. In rural areas, the density of polluting transportation sources is low enough that it can generally be dissipated into the atmosphere. As population increases in these areas, they too will face decreased air quality.

### Incineration

Waste is commonly incinerated, especially in rural and suburban areas. This practice is efficient in reducing the volume of the waste, but it greatly degrades air quality. The most abundant pollutant in smoke is particulate. The composition of the particulate varies considerably, depending on what is being burned. The particles are called fly ash and can be dispersed many miles from the source, a smokestack. Fly ash can contain hazardous substances including heavy metals such as lead, chromium, and arsenic and organics such as PAHs, polychlorinated biphenyls (PCBs), and dioxin. Even in small amounts,

Pie charts showing the sources of major air pollutants and relative amounts averaged from 1990 to 1998

these substances can cause health problems for susceptible people. For this reason, there are now federal and many local statutes controlling the amount and composition of smokestack emissions. They must be fitted with pollution-reducing devices, generally scrubbers, and they are permitted to release only a given volume of emissions, depending upon the local environment and the type of emissions.

**aldrin/dieldrin** Second only to dichlorodiphenyltrichloroethane (DDT) in application, aldrin/dieldrin are powerful and formerly widely used pesticides that were also irrevocably banned. They seem to have escaped the notoriety of DDT, even though they are more toxic. They did not go entirely unnoticed in popular culture, however, as they were used as a murder weapon in an episode of the popular television series *Law and Order: Special Victims Unit*. Invented in the 1940s, aldrin and dieldrin were used extensively throughout the 1950s and 1960s, achieving peak production of about 20 million pounds (9.1 million kg) per year by the late 1960s.

Aldrin and dieldrin are actually two separate but structurally similar compounds that were both used as insecticides. Aldrin is really not very dangerous as is, but it readily breaks down to dieldrin, both in the natural environment and in insects and other life-forms. Dieldrin is highly toxic to most life and has extreme persistence in the natural environment. Trade names for aldrin include Aldrec, Aldrex, Drinox, Octalene, Seedrin, and Compound 118, and dieldrin was sold as Alvit, Dielatrix, Octalox, Quintox, and Red Shield. Aldrin has been found in

207 of the first 1,613 U.S. Environmental Protection Agency (EPA)–designated Superfund sites on the National Priorities List (NPL) for which it was tested, and dieldrin has been found in 287 of the first 1,613 sites. Aldrin is number 24, and dieldrin is number 17 on the 2007 CERCLA Priority List of Hazardous Substances, which includes 275 entries. Both aldrin and dieldrin pose very grave environmental threats.

#### PROPERTIES AND USES

Aldrin and dieldrin are chlorinated hydrocarbons that do not occur naturally. The technical name for aldrin is 1,2,3,4,10,10-hexachloro-1,4,4 $\alpha$ ,5,8,8 $\alpha$ -hexahydro-1,4-endo,exo-5,8-dimethanonaphthalene, or HHDN, and dieldrin is 1,2,3,4,10,10-hexachloro-6,7-epoxy-1,4,4 $\alpha$ ,5,6,7,8,8 $\alpha$ -octahydro-1,4-endo,exo-5,8-dimethanonaphthalene, or HEOD. Both are white to tan powders as chemicals, but, as insecticides, they were marketed as emulsifiable concentrates, wettable powders, dusts, and granules. Aldrin was used as a soil insecticide for beetles, rootworms, and termites. Dieldrin was largely used in agriculture as a soil and seed treatment, as a wood treatment, and as mothproofing for wool, as well as directly on insects such as locusts, mosquitoes, and tsetse flies. Both were used on crops such as corn and cotton and in specific applications for beans, onions, sugar beets, nursery stock, and ornamental and fruit bushes and trees, among others. In 1970, the U.S. Department of Agriculture banned all uses of aldrin and dieldrin because of their toxicity, but, in 1972, EPA approved the use of these pesticides for residential and commercial control of termites. This practice continued until 1987, when even this use was banned and the manufacturer voluntarily stopped production.

#### ENVIRONMENTAL RELEASE AND FATE

As with most pesticides, both substances were ultimately released into the environment, generally entering the soil and groundwater as nonpoint source pollutants. Now, since the ban has been enforced, they only leak from storage facilities and waste sites. From a regulatory standpoint, current discharges are considered to originate as point source pollutants. This is because they were used on specific locations for a specific purpose (such as agricultural fields). Industrial releases of aldrin in 2005 totaled a mere 3,440 pounds (1,564 kg) with no reports of dieldrin release. It would appear that aldrin and dieldrin should no longer be substances of concern, but in fact almost all Americans are still exposed to them on a regular basis. There is probably very little aldrin

left in the natural environment, because sunlight, bacteria, insects, and animals convert it to dieldrin. Dieldrin, however, is one of the most persistent environmental contaminants known and among the top 10 percent in terms of danger to the ecosystem and human health. The estimated half-life for dieldrin is from 175 days to more than three years, but it is still found in the soils to which it, or aldrin, was applied some 37+ years later. When they were applied to soil, some aldrin and dieldrin evaporated slowly into the atmosphere, aldrin a bit more quickly than dieldrin. Most of that which evaporated attached to dust particles and was widely distributed. The aldrin converted to dieldrin and dieldrin changed to photodieldrin within a few days. That which remained in the soil attached strongly to soil particles and remained fixed indefinitely. Very little, if any, leached into the groundwater system, and very little has ever been found there. In surface water, that dieldrin which did not evaporate attached to particles and settled into the sediment and remained fixed.

Plants provide the only way to remove dieldrin from soil and sediments. They absorb it through their roots and spread it throughout the plant. Animals can then eat the plants and ingest the pesticide. Dieldrin is highly toxic to bees, aquatic organisms, birds, and especially mammals. It collects in their fatty tissue among other organs and can be passed to humans in both meat and vegetables. It also collects in the fat of human breast milk, where it has been known to concentrate at 10 or more times ambient levels. It was found in 99 percent of breast milk samples from around the world in a survey taken during peak usage. Shellfish that filter sediment can also accumulate dieldrin. These two sources are the main way it enters the human body.

### HEALTH EFFECTS FROM EXPOSURE

There are many adverse health effects of dieldrin exposure. Acute exposure is marked by symptoms of the central nervous system including dizziness, headache, irritability, and periodic and continuous convulsions, leading to possible brain damage, coma, and death if the dose is high enough. It can also cause nausea and vomiting. Long-term chronic exposure has similar effects, as well as kidney and liver damage, tremors, muscle spasms, depression, anxiety, sleep disturbance, impaired memory, weight loss, weakness, immune system damage, infertility, damage to developing fetuses, high infant mortality, and a strange condition in which the body destroys its own red blood cells. The EPA and Department of Health and Human Services have designated aldrin and dieldrin as probable human carcinogens. It has

been shown to increase the incidence of tumors of the kidney, lungs, liver, mammary glands, and lymphatic system of laboratory animals, but most were benign. Only the liver was found to be cancerous in mice but not in other animals.

### REGULATION ON HUMAN EXPOSURE

Aldrin and dieldrin were among the earliest regulated environmental substances. The EPA limits aldrin and dieldrin in drinking water to very low levels: 1 and 2 mcg per liter, respectively, under the Safe Drinking Water Act. If one pound (0.45 kg) or more is released to the environment, EPA requires reporting to the National Response Center. The Occupational Safety and Health Administration (OSHA) set its permissible exposure limit (PEL) at 250 mcg of aldrin and dieldrin per cubic meter of workplace air for an eight-hour-day, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) set the same 250-mcg limit for 10 hours, as well as an Immediately Dangerous to Life and Health designation of 25 and 50 mcg of aldrin and dieldrin, respectively, per cubic meter of workplace air. By 2003, more than 50 countries had banned or severely restricted the use of aldrin and dieldrin, and 100 countries banned the import of these pesticides. The result of the regulations is that the concentration of aldrin and dieldrin in breast milk has been reduced at least 75 percent and commonly 90 percent from its late-1960s levels.

### **Amoco Cadiz oil spill Ouessant, France (March 16, 1978) Water Pollution**

Amoco (American Oil Company–Standard Oil of Indiana) had major operations in oil transportation operating under the name of Amoco Tankers and Amoco Transport. As Middle Eastern oil started to become a significant factor in the market, the company commissioned the construction of two supertankers to establish a strong position in transportation. A supertanker is a vessel that is capable of carrying more than 2 million to 3 million barrels (318 million–477 million L) of crude oil. The shipbuilder, Astilleros Españoles, S.A., the same company that had constructed the *Nina*, *Pinta*, and *Santa Maria* for Christopher Columbus, laid the keel for the first of the Amoco's tankers the *Cadiz*, named after the town in which it would be built. Construction of the *Amoco Cadiz* began in May 1970 and took four years to completion. The ship was almost 1,100 feet (338 m) long and 170 feet (52 m) wide, so large that three college football games could be played simultaneously on its decks, with plenty of room to spare. It had a cargo capacity of 234,000 deadweight tons (213,000 metric tons) and could carry 1.6 million barrels (67 million gallons, or 255 million L) of crude oil. Powered by a 30,000-horsepower diesel engine driving a single screw or propeller, the *Cadiz* could travel at up to 15 knots (28 km/h, or 17 miles per hour) and required a crew of only 44 to operate it.

During shipbuilding, both Amoco and the American Bureau of Shipping (ABS) conducted regular inspections and testing of equipment, both to ensure conformance with design specifications and to make necessary changes required during construction. The ABS is a not-for-profit organization that develops and evaluates rules and standards for shipbuilding, including operating designs and eventual seaworthiness. Even for such a huge size, the *Cadiz* was steered by a single, hydraulically driven rudder. In its simplest form, a rudder is a flat piece of metal or wood mounted vertically to the bottom of the ship that can be turned to the right (starboard) or left (port) by a helmsman and is used to redirect the flow of water past the hull. When under way, the ship moves in the same direction as the rudder is turned.

The rudder on the *Cadiz* was a massive device and could only be turned by using a specially designed

hydraulic steering engine. This engine operated two pairs of rams, or metal pushrods, sealed inside four fluid-filled cylinders. The four steel rams had cast-iron tops, or heads, that mechanically adjusted or pushed the rudder in the direction determined by the helmsman. When a course correction or docking maneuver was required, the helmsman (or autopilot) turned the wheel, producing an electrical impulse that was transmitted to a set of hydraulic pumps. These pumps added or removed hydraulic fluid from the ram cylinders, which, in turn, changed the position of the rams, and the ship changed course as the rudder moved.

The hydraulic steering system was a critical safety feature and vital to the ship's survival. Without the constant pressure of hydraulic fluids in the cylinders, which kept the rams pressing against the rudder linkage, the steering of the ship could not be controlled. No backup or secondary maneuvering systems were designed or installed in the *Cadiz*. On twin or dual screw ships, if the rudder fails, the vessel can still have limited maneuverability by the helmsman's varying the speed and direction (forward or reverse) of the propellers. The *Cadiz* had only one screw and only one rudder. Even the *Cadiz*'s anchor was too small to be useful in stopping the ship, designed only to hold her steady during loading and unloading.

The *Cadiz* was placed into service in 1974. The ABS had certified all components of the ship, including its hydraulic steering system, as seaworthy. Periodic inspections by ABS over the next three years did not find any major problems with the rudder control mechanisms. Almost immediately, the *Cadiz* was chartered to Shell International Petroleum Corporation to move petroleum from the Middle East to refineries in Europe. Under the terms of the charter, Amoco was responsible for the ship's maintenance, and, when it was being serviced or repaired or was inoperable because of equipment failure, no payments were to be made by Shell to Amoco. Under this arrangement, it was in Amoco's best interest to keep the *Cadiz* in service as much as possible. Even though the vessel was originally scheduled to be dry-docked every year for major repairs and overhaul, Amoco decided to extend these service intervals to every 30 months, thus saving hundreds of thousands of dollars in dry-docking and charter fees.

### **THE ACCIDENT AND SPILL**

In February 1978, a full load of crude oil was pumped into the huge cargo holds of the *Cadiz* from storage terminals, first, at Kharg Island, Iran, and then at Ras Tanura, Saudi Arabia. The ship sailed southward, through the Red Sea, down the east

coast of Africa, around the Cape of Good Hope, and then northward, up the west coast of Africa toward Europe and Rotterdam, its final destination. Representatives of Marine Safety Services, a British company conducting training and safety classes in ship operations for the *Cadiz* officers and crew, were on board. On March 15, within a day or so of its destination, the weather deteriorated, and the *Cadiz* began to roll and pitch in heavy seas. By the next day, the waves and winds were near hurricane conditions. Despite the storm, the ship performed flawlessly, with the helmsman firmly in control of her speed and direction.

On the morning of March 16, just as the *Cadiz* entered the English Channel off the northwest Breton coast nine miles (14.4 km) west of the French island of Ouessant, a series of events took place in the engine room that resulted in the catastrophic failure of the steering control mechanism. After a call from the bridge to the engine room that the ship did not seem to be responding, crew found that five of six bolts on the flange of a hydraulic oil pipe on the port-side steering pump had been sheared off. Hydraulic fluid was gushing from the pipe, and air was entering the steering system. As hydraulic fluid continued to leak from the pipe, the rams that maintained control of the ship's rudder began to lose pressure. Without the rams to control its movement, the rudder began to shift back and forth in the rough seas. As the crew worked frantically to repair the leak and purge air from the steering system, another hydraulic pipe failed, and the rudder, now completely out of control, swung violently back and forth, tearing apart the steering control mechanism and sending metal shrapnel flying throughout the engine room. One crewman was injured, and the chief engineer ordered the engine room evacuated. He then informed the captain that the steering mechanism could not be repaired and that the ship was out of control. The captain radioed for assistance, and the *Pacific*, a German salvage tug, responded.

When a ship, her cargo, or her crew is in danger, the owner or master of the ship can call for help from a marine salvage vessel. These large and powerful oceangoing tugs or repair ships put themselves in peril for a percentage of the value of the ship and/or the cargo being saved. Salvage can take the form of refloating a grounded ship, patching a breach in the hull, repairing a critical mechanical system, or towing a disabled ship to a port or dry dock. Within the last 30 years or so, the definition of salvage has expanded to include protecting the environment by preventing or minimizing the release of a ship's cargo, especially if it is oil or some other substance that might damage the marine environment.

The oil tanker *Amoco Cadiz* sinks off the coast of Brittany, France, on March 16, 1978. (NOAA)

The captain of the *Pacific* offered salvage assistance to the *Cadiz* under the terms of a Lloyd's Open Form (LOF) "No-Cure-No-Pay" contract. The main principle of this contract is that if the *Pacific* failed to save the *Cadiz*, the *Pacific* would not be entitled to any compensation, even if the *Pacific* were damaged or sunk during the salvage attempt. Also, under the Lloyd's Open Form, the price or payment for salvage assistance is decided after the damaged vessel has been secured safely and the parties can more calmly discuss the basis for the claim. In the case of the *Cadiz*, given the value of the ship and its cargo (about \$40 million), the monetary worth of the salvage claim would have been significant.

Before the captain of the *Cadiz* could accept assistance from the *Pacific*, he had to call Amoco's headquarters in Chicago for permission. As the parties negotiated, the *Cadiz* drifted closer and closer to the rocky coastline. Finally, after more than four hours of negotiations and when the *Cadiz* was only six miles (9.6 km) from Ouessant, an agreement was reached and the *Pacific* began salvage operations. Approaching the *Cadiz* through very rough seas, the *Pacific*, with the help of some brave *Cadiz* crewmen, was able to secure a towline to the bow. However, by now the *Cadiz* was pitching and rolling so violently that the bow would disappear below the surface, and the *PACIFIC*'s attempts to turn the *Cadiz* into the wind and tow her a safe distance out to sea were unsuccessful. The towline snapped, as did a second one that was attached to the stern of the *Cadiz*.

By now, the currents and winds had pushed the *Cadiz* up against the coast, and it began to roll and pound against the rocks and shallow bottom of the shoreline. The *Pacific* had to break off the salvage attempt, and at 9:40 p.m. the *Cadiz*'s hull stove in

and the *Pacific*'s captain's log noted that the air began to smell of oil. The crew was evacuated by helicopter, except the captain and one senior officer, who were taken off the next morning. An estimated 15 million gallons (68 million L) of crude oil was released from the *Cadiz* within 24 hours of its grounding. Eight days later, the *Cadiz* had been torn into pieces and spilled its entire 60-million-gallon (227-million-L) crude oil cargo onto the coastline of Brittany, one of the most ecologically sensitive and popular vacation places in France. Eventually, using depth charges, the French navy destroyed the remaining pieces of the wreck as a hazard to navigation. Later, Amoco would sue the owners of the *Pacific* for failing to rescue the *Cadiz* and for not preventing the oil spill. The French courts dismissed the claim.

### **CLEANUP AND ENVIRONMENTAL DAMAGE**

The oil slick from the *Cadiz* eventually covered 25 percent of the Breton coastline, extending 80 miles (128 km) in length and 18 miles (29 km) in width. More than 4,000 people and 50 ships participated in cleanup operations, which took more than six months. Both the British navy and the French army, along with hundreds of volunteers from all across France, used heavy machinery, shovels, and sometimes mops and buckets to remove 220,000 tons (199,600 metric tons) of oily waste the color and consistency of chocolate mousse that had covered the beaches. The oil destroyed the delicate ecosystem along the coastline, obliterating oyster and lobster beds. Thousands of seabirds died, and 30 percent of France's seafood supply was put at risk of contamination. In addition, kelp and algae that usually were harvested for fertilizer and animal feed supplements were destroyed. The overall loss in terms of fishery and tourism was an estimated \$100,000,000.

Cleanup was helped by waves and winds that dispersed and evaporated much of the oil. These same waves and winds that pushed the *Cadiz* to her destruction also helped provide nutrients and oxygenated water to the naturally occurring bacteria that slowly biodegraded the oil. Within three years of the *Cadiz*'s grounding, most of the major effects of the oil spill were not noticeable along the coastline. Oil that had been pushed into more protected inlets, however, could still be detected more than 10 years after the spill.

### **THE AFTERMATH**

The proximate causes of the spill were a failed hydraulic line and bad weather. The investigations carried out during the subsequent legal actions and

lawsuits associated with the wreck of the *Cadiz*, however, revealed a much larger, systemic problem with Amoco's policies relating to the design, operation, and maintenance of the ship.

Cast-iron metal bushings (sleeves) were used to line the cylinders that the steel rams of the rudder control traveled through. Cast iron is harder than steel, and as the rams moved back and forth through the bushings, dirt trapped inside the cylinders scored or grooved the surfaces, causing a drop in hydraulic pressure and steering mechanism efficiency. Amoco was aware of the potential problems caused by the cast-iron bushings but had elected to accept a partial refund from the shipbuilder rather than take the ship out of service to replace the bushings. In fact, a replacement set of bronze bushings was onboard waiting to be installed when the *Cadiz* went aground.

Amoco also did not regularly follow manufacturer recommendations that the ram cylinder isolation valves be exercised (opened and closed) and lubricated periodically. If these valves had been working, the engine room staff would have been able to shut down part of the hydraulic steering mechanism and perhaps damp or "brake" the runaway rudder with the remaining functioning rams. Divers recovered the open cylinder isolation valves from the sunken wreck of the *Cadiz*, and French inspectors found that the stem threads had been painted. The valves could not be fully closed because of the presence of this paint on the thread mechanism.

Hydraulic oil should have been properly filtered before being added to the reservoir tank. The in-line oil filters needed to be checked to make sure they were functioning properly, and the oil had to be tested for the presence of water and other contaminants. The reservoir tank also had to be emptied and cleaned periodically to prevent the buildup of sludge. Amoco did not follow any of these maintenance recommendations, primarily because they would have required an interruption in ship's operations. The continued use of impure and partially spent hydraulic oil decreased the system's lubricating ability and probably contributed to the failure of steering controls. A blockage in one of the steering mechanism valves clogged the system. Hydraulic fluid added by engine room mechanics during their attempts to replace the oil being lost through the broken flange simply overflowed out of the top of the reservoir tank. Investigators also found that the crew had not been trained in these and other maintenance procedures, and they had never been drilled in emergency procedures related to a rudder system failure.

These and other operational and maintenance lapses were the direct result of Amoco's unwillingness to accept the loss of income that would

occur during dry-docking and overhaul downtimes. The U.S. courts admonished Amoco for their frugal approach to operations and in a 1988 settlement awarded France \$85.2 million in damages. Both sides appealed, and, in 1990, the courts agreed that the monetary award should be increased to \$120 million. Since then, Amoco and its later owner, BP, have worked to improve maintenance procedures and crew attitudes toward tanker safety.

**Anniston Army Depot Anniston, Alabama (1990–1997) Soil Pollution** Anniston is a small town in northeastern Alabama, about 110 miles (177 km) west of Atlanta, Georgia. It is host to a 15,000-acre (6,070-ha) state-of-the-art industrial center with more than 2,600 employees, 260 miles (418.4 km) of roads, and almost 90 miles (144.8 km) of fence line. Since February 1941, Anniston Army Depot has been storing, managing, repairing, and overhauling munitions, including missiles and artillery, small arms, and combat vehicles, including tanks and trucks. The depot contains an ammunition storage area, an industrial plant where most of the vehicle maintenance and equipment restoration activities take place, and an administrative/housing area. The 1,300 ammunition storage bunkers make up more than 90 percent of the site, with the industrial area occupying about 500 acres (202 ha) in the southeast corner of the facility.

The ongoing work at Anniston is essential to national defense and involves the use of degreasers, paints, acids, and solvents as well as petroleum

products such as lubricating oils and fuels, heavy metals, and explosive compounds. Until the early 1980s, facility operators followed standard industrial practices and disposed of most of the wastes generated at the site by burying or placing them in landfills and trenches, sometimes after performing rudimentary processing or treatment and detoxification in lagoons or sumps. Many of these materials, or their breakdown products, have migrated from these landfills and trenches and contaminated soil and groundwater at the site. Since 1981, the Anniston Army Depot has shipped its hazardous waste to licensed off-site disposal facilities.

#### POLLUTED SITES

The long and challenging process of identifying and remediating contaminated soil and groundwater at Anniston began in the 1980s as part of the U.S. Army's nationwide Installation Restoration Program. Working in close cooperation with the U.S. Environmental Protection Agency (EPA) Region IV office and the Alabama Department of Environmental Management, the Anniston Ammunition Depot began to address the approximately 90 waste disposal areas on the property, including spill areas, landfills, and chemical lagoons. There were also several specific polluted sites noted, as follows:

- *Valve disposal pit.* Approximately 10,000 sodium-filled tank engine valves were buried in this pit in 1947. Sodium is a very effective heat transfer fluid but is extremely reactive, especially when exposed to water. Sodium's reaction with water is exothermic and produces very caustic sodium hydroxide and highly flammable hydrogen gas.

**Chemical demilitarization processing facility at Anniston Army Depot, Alabama, 1998** (Robert P. Mayfield/Defense Visual Information Center)

- *Calcium hypochlorite burial pit.* Used for the disposal of 400 100-pound (45.4-kg) containers of calcium hypochlorite. Calcium hypochlorite is an oxidizer and can be a fire hazard when mixed with organic materials. If acidified, it also can release chlorine gas.
- *Chemical disposal pit.* Tanker-truck quantities (2,000–5,000-gallon or 7,571–18,927-L batches) of a variety of chemical wastes were poured into this pit from the late 1940s until possibly as late as 1972.
- *Metal plating shop.* Operations in this building included metal cleaning, treating, and plating. High levels of chromium have been found in soil, surface water, and groundwater adjacent to this structure, possibly released by spills or leakage from waste sumps and carried on dust discharged through the ventilation system.

### REMEDIAL ACTIVITIES

Several remedial activities have been implemented at the Anniston depot. Contaminated soil and sediment has been excavated or dredged from spill areas and streambeds, and sludge from waste pits and lagoons has been removed. A groundwater pump-and-treat system was installed and began operation in 1990 to prevent the off-site migration of groundwater containing organic solvents.

Among the most difficult disposal systems to remediate are the three industrial waste lagoons that stored solvent wastes. These lagoons were closed and backfilled with clay in 1978. About 72,000 pounds (32,659 kg) of trichloroethene (TCE), a volatile organic chemical, is believed to remain in the former storage basins. The highest TCE concentrations (20,100 mg/kg) are present at a depth between eight to 10 feet (2.4–3.1 m). In 1997, Anniston launched a concentrated remediation effort on the contaminated soil in the lagoons. Using 225 injector wells, 109,000 gallons (412,610 L) of peroxide, supplemented with trace concentrations of ferrous sulfate and acid, were introduced into the subsurface over a 120-day period.

Liquid peroxide solution is a quick and often cost-effective method for chemically oxidizing pollutants present in subsurface soil. In this process, hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) generates hydroxyl radicals that directly oxidize soil contaminants. Typically, the peroxide is introduced in a water mixture through specially designed injection wells. In order to accelerate the chemical oxidation, a metal catalyst, most

commonly iron, is added. This mixture of peroxide and iron is known as Fenton's reagent, named after Henry John Horstman Fenton, a Cambridge, United Kingdom, chemist and professor who developed the method in the late 1800s. The combination of iron and peroxide significantly increases the number of free radicals and thus the oxidative power of the solution.

The hydroxyl radicals are extremely strong oxidizing agents, capable of rapidly attacking and breaking the carbon-to-carbon chemical bonds of most organic compounds, usually within minutes after its application. Oxygen is also released during peroxide decomposition and can encourage bioremediation. The effectiveness of Fenton's reagent is tied directly to the permeability and pH of the soil. The higher the permeability, the more quickly the reagent can react with the contaminant. Fenton's reagent loses its effectiveness in calcite-rich alkaline soil. These are soils where carbonate ions ( $\text{CO}_3^{2-}$ ) can rapidly scavenge the hydroxyl radicals as fast as they are produced during the oxidation process.

At Anniston, 25 deep wells were installed to monitor the chemical oxidation process and to serve as a venting system to help ensure an effective radial distribution of the peroxide. Postinjection sampling data indicated that the chemical oxidation process lowered the soil contaminant concentrations from 1,760 mg/kg to below laboratory method detection levels. Data from monitoring wells indicated that migration of contaminants to either surrounding soil or groundwater had not occurred during the remediation process.

Despite these and other cleanup efforts, Anniston Army Depot was added to the National Priorities List (NPL), or Superfund sites, by the EPA in 1989, primarily because of the soil and groundwater pollutants present on the site as a result of its long history of in-ground chemical disposal (1950 through 1981). Remedial activities continue today, and the army estimates that Anniston will be cleaned up and removed from the NPL by 2031.

**antifouling paint** The hull is the part of the ship that is below the main topside (above water) decking. It generally consists of an outside covering or skin, sometimes called plating, made of wood or metal and an inside framework to which the skin is attached. In most commercial oceangoing vessels, the skin and framework usually are made of steel and connected to each other by welds or metal rivets. An essential part of the ship, the hull keeps the vessel afloat, protects the ship from floating objects that could damage it, and secures the space into which cargo, engines, and other ship's infrastructure are placed.

The outside of the hull also provides substrate for the colonization and growth of both sessile (fixed) and mobile (floating) marine organisms. When these organisms accumulate on the submerged part of the ship to the point where they begin to affect its performance, the hull is said to be fouled.

Hull fouling organisms are those that are typically found in the intertidal and subtidal zones of continuously submerged marine settings. These organisms include arthropoda, such as barnacles, amphipods, and crabs; mollusca, such as mussels, clams, and sea slugs; porifera, or sponges; bryozoa; cnidaria, such as hydroids and anemones; protozoa; marine worms; and chordata, such as sea squirts and fish, as well as seaweed. Fouling organisms tend to concentrate in sheltered areas of the hull, such as sea chest intakes and rudder posts. Sea chests are openings in the ship's hull below the waterline used for the controlled intake and discharge of the ship's cooling system water. Sea chests often have blowout holes through which blasts of air or steam are sent to clear obstructions to water flow. Slow-moving vessels such as towed vessels like cargo barges, floating dry docks, or oil rig platforms are more likely to develop fouling organisms.

Organisms attached to the hulls of ships are a significant problem. Hull fouling increases fuel con-

sumption by as much as 20 percent and can cost a ship's owner thousands of dollars in additional fuel costs. The U.S. Navy spends more than \$200 million every year in extra fuel and maintenance (removal and repainting) related to biofouling organisms. In addition, fouled hulls provide a mechanism for potentially troublesome and disruptive aquatic species to travel from one port to another.

## PROPERTIES OF THE PAINT

Mariners have used a variety of techniques to prevent or at least slow biofouling. Early sailing ships coated their hulls with lime or even arsenic to reduce the attachment and growth of algae and mollusks. Since the 1970s, special antifouling paints (also called bottom paints) have been developed that slowly release a growth inhibiting substance or poison, called organotin or tributyltin (TBT;  $C_{24}H_{54}OSn_2$ ), a substance containing both the metallic element tin and carbon. TBT is chemically bound within the matrix of the paint. As the ship moves through the water, the paint is worn away in a process called self-polishing and the TBT is slowly released. This self-polishing action works even when the ship is moored as long as tidal currents or wave action in the harbor provide sufficient water movement across the hull.

TBT-impregnated paint is used on most commercial and many military vessels. Commercial and recreational marine facilities that routinely wash and repaint ships' hulls use high-pressure cleaning techniques that often flush TBT-bearing paint residuals into harbor or marina waters.

## ENVIRONMENTAL PROBLEMS

TBT recently has come under ecological scrutiny. It is non-water-soluble, or hydrophobic, and it is readily absorbed by marine harbor and ocean water sediments, especially in heavily trafficked ports and shipping lanes. TBT is moderately persistent in sediment, with a removal half-life of months to years, or even longer under anaerobic (oxygen-deficient) settings, and it can be ingested by bottom-dwelling marine organisms. It has been found to bioaccumulate in fish, seabirds, and marine mammals, in which it can damage reproductive or immune systems. It interferes with cell growth, development, reproduction, and immune response and distorts mitochondrial membranes. In marine invertebrates, TBT may alter endocrine (hormonal) functions. A study by the Dutch Institute for Marine Research and the Free University of Amsterdam found TBT and its breakdown products in sperm whale tissues,

suggesting that TBT may be widely dispersed in the marine environment.

These well-documented negative impacts of TBT on marine life have led to an abandonment of its use. As a result, a number of more environmentally friendly alternatives are being developed. The U.S. Navy currently uses copper-based ablative coatings that can be removed or vaporized at high temperatures. These coatings rely on the toxic effects of cuprous oxide to prevent or reduce the growth of marine organisms. This is a short-term solution, as copper-based paints also concentrate in marine sediments and need to be reapplied every two to three years, as compared to about five to seven years for TBT. A more promising bottom paint alternative may be silicone-based coating systems.

**antimony** Antimony is an inorganic heavy metal that occurs naturally in various rocks and minerals as well as around certain industrial sites and landfills. Antimony ore is mined as the mineral stibnite ( $\text{Sb}_2\text{S}_3$ ), primarily to be mixed with other metals to produce alloys. Alone it is too soft and brittle for most applications, but it can strengthen, harden, and add fire resistance to other materials. It is most commonly mixed with lead to improve battery performance (life and voltage), but it is also used as a primary component in matches, as a lead substitute in solder, in tracer bullets, as a primary flame retardant in numerous items from textiles to plastic toys and covers, in medicines from antiparasite medications in the past to antischistosomal drugs, in the semiconductor industry for numerous applications including diodes and infrared detectors, and in numerous metal

alloys, many with low friction properties. Antimony, however, can be an environmental hazard that has been found to occur in 403 of the first 1,416 U.S. Environmental Protection Agency (EPA) Superfund sites on the National Priorities List. As the result of this widespread distribution as well as adverse health effects from exposure, antimony is ranked 219 of the top 275 most dangerous pollutants on the 2007 CERCLA Priority List of Hazardous Substances.

For economic reasons, very little antimony is mined in the United States. More than 80 percent of all antimony is produced in China; Bolivia, South Africa, Russia, and Tajikistan are the next top producers in decreasing order. Approximately 135,000 tons (122,727 metric tons) of antimony were produced in 2007, up from 106,000 tons (96,364 metric tons) in 1994.

#### ENVIRONMENTAL RELEASE AND FATE

Between 1987 and 1993, nearly 12.5 million pounds (5.7 million kg) of antimony were released into the environment in the United States. The top 10 states reporting antimony releases were Arizona, Montana, Texas, Louisiana, Wisconsin, Missouri, Washington, Idaho, Tennessee, and Alabama. In 2005, some 12,597,353 pounds (5,726,070 kg) of antimony and antimony compounds were reported to have been released into the environment by industry. The industries that release antimony are primarily metal smelting and refining, but also organic chemical production and the manufacture of porcelain plumbing fixtures. Other uses of antimony include petroleum refining, inorganic chemical production, plastics, batteries, and synthetic fibers. Small amounts of antimony also are released by coal-burning power plants and incinerators.

If antimony is discharged in smokestack emissions, particles can attach themselves to other particulate matter and settle to the ground and surface water. Although most sink quickly to the ground, some may remain airborne for longer than one month. Very little antimony can be dissolved in water because of its metallic nature, typically less than five parts per billion (ppb). Usually, it attaches to particles and settles into sediment. Even though it is used for solder in home plumbing, it rarely enters drinking water. It does not appear to bioaccumulate and is seldom found in soil. It exists there typically at concentrations of less than one part per million (ppm). Antimony usually attaches itself to clay and organic material and is not easily dissociated (removed) from these fine grains of sediment and soil. Around antimony processing sites and at industrial waste sites, on the other hand, antimony concentrations have been known to

reach 2,550 ppm, primarily from improper waste management and air pollution fallout.

### HEALTH EFFECTS FROM EXPOSURE

Acute exposure to antimony can produce a number of adverse health effects through both inhalation and oral ingestion. Ingestion of antimony typically causes gastrointestinal distress, including vomiting and diarrhea; respiratory difficulties; and death at high dosages. Inhalation produces the same gastrointestinal response as well as pulmonary edema and death at elevated levels. Contact exposure of antimony has been shown to cause rashes in some test animals and even death in a few cases as well as eye irritations in humans. Long-term chronic exposure to antimony produces respiratory problems including pneumoconiosis and restrictive airway disorders and cardiovascular problems such as changes in blood pressure and electrocardiogram abnormalities. It also has been shown to cause hematologic (blood) disorders, liver and kidney problems, and possible reproductive problems such as alterations in the menstrual cycle and increased spontaneous abortions, as well as decreased life span. Long-term inhalation of antimony has resulted in increased lung tumors in some laboratory animals, but the data are still inconclusive for human exposure.

### REGULATIONS ON HUMAN EXPOSURE

The clear health implications of antimony exposure have led federal regulatory agencies to set recommended limits on exposure to it. The EPA set the drinking water limit at 6 ppb, above which corrective action must be taken. The EPA limit for water in lakes and streams is 145 ppb. There also are limitations on the amount of antimony that can be released to the environment by industry. The Occupational Safety and Health Administration (OSHA) established a limit of antimony in air to 0.5 mg per cubic meter of air during an eight-hour-work day, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) similarly recommends a maximum of 0.5 mg per cubic meter of air averaged over an eight-hour workday. They also set a designation of immediately dangerous to life and health (IDLH) of 50 mg per cubic meter of workplace air.

**aquifer** An aquifer is a layer of rock, sediment, or soil or a zone within these layers that is capable of yielding water in large enough quantities to be useful. What constitutes a useful quantity depends upon the need to be served. Some aquifers are hundreds of feet thick and can serve areas the size of states or multiple states, but for a single house, even a small aquifer may be sufficient. In order for the rock or sediment to be an aquifer, it must have porosity to store water, but, most of all, it must have permeability so the water can flow. Water is pumped out of the aquifer through a penetrating well. The water removed must be replaced by other water in the aquifer quickly enough to prevent the well from going dry. The best type of material for an aquifer is a large unlithified or weakly lithified beach sand-type deposit. In New Jersey, the Kirkwood-Cohansey sands form a huge aquifer of relatively unconsolidated beach sand. The famous Ogallala Aquifer, which supplies water to South Dakota, Wyoming, Nebraska, Colorado, Kansas, Oklahoma, New Mexico, and Texas, is the largest single aquifer in the United States and is composed of weakly consolidated river sand and gravel.

In each of these cases, water is carried in the open spaces between mineral or sediment grains, which provide the primary porosity of the material. Infiltrating water travels in a circuitous route around individual sediment grains as it settles deeper into the earth under the force of gravity. The water reacts chemically with the surface of the grains, dissolving some chemical compounds while precipitating others. In this way, pollutants and other ions can be removed from the water, and other compounds can

be added. “Hard” water is produced by chemical species that capture ions, primarily calcium carbonate (calcite or lime). The finer the grains in the aquifer sediment, the more surface area the water makes contact with and the more chemical exchange and purification takes place. The infiltrating water must squeeze between grains that are in contact. The necks formed by these grain contacts are so narrow that not all components of the infiltrating groundwater can pass through. In particular, bacteria, viruses, and solids are filtered out in these passages. It is by these filtering processes that groundwater is purified into potable water for household use.

In contrast to an aquifer, an aquiclude has very little to no permeability. As such, groundwater will not be able to flow through it, regardless of its porosity, which can be quite variable, and therefore it is not used for water production. Typically, aquicludes are composed of shale or dense clay, although they can be of other rock and sediment types as well. Under the right orientation relative to gravity, aquicludes may bind and thus seal aquifers, allowing the water pressure to increase in them as in a garden hose. This geometry is called an artesian system. If

an aquiclude has minor permeability and flows small amounts of water, it is called an aquitard, which is like a leaky aquiclude. These units may produce water for small applications but cannot be major water producers.

There are typically two aquifers in most areas. The unconfined or shallow aquifer is a water-bearing layer that extends to the ground surface. It typically is composed of soil and contains the water table for the area if rainfall is plentiful. This was the layer in which wells were historically dug by hand and water was retrieved by means of a hand pump or bucket. The problem is that most surface and subsurface spills of any number of noxious liquids ranging from leaking septic and oil tanks to herbicides and pesticides will quickly filter down into the water table, rendering this aquifer polluted and the water not potable. Few people utilize the shallow aquifer in populated areas. The exception to this occurs in coastal areas, where deeper waters are saline. It is this dependence on water from the shallow aquifer or surface water that interacts with the shallow aquifer, which is invariably of poor quality, that causes many of these areas to be cancer alleys.

**Fern Hammock Springs in Ocala National Forest, central Florida—an artesian spring of the Floridian Aquifer** © Raymond Gehman/CORBIS)

Deeper aquifers are typically confined between nonaquifer layers and require drilling to access them. Water must travel a long distance filtering through many rock and soil types to reach this aquifer from the surface. It makes contact with many mineral surfaces, where contaminants can be removed. The water also filters through tightly packed grains and fragments, which remove the bacteria and viruses. Water in confined aquifers is typically clean and provides abundant community and private well water. Confined aquifers, however, are not safe from pollution. Some pollutants are denser than water (DNAPLs dense nonaqueous phase liquids) and filter more quickly than water to these deeper aquifers. Most of these aquifers get the majority of their water from some distant location where the aquifer unit breaches the surface. These areas are called aquifer recharge zones. Any surface pollutants there will slowly contaminate the aquifer and eventually make it unusable, and a still deeper aquifer must be found.

Deeper aquifers may not have the same permeability as shallow aquifers because the rocks are subject to cementation by ion-bearing fluids and compaction by overburden. Deeper fluids may be more saline in some areas and tend to have higher radon levels than shallow waters.

### FRACTURED ROCK AQUIFERS

Crystalline metamorphic and igneous rocks do not have primary porosity and permeability. The mineral grains are knit too tightly together and leave no room for pore space. These rocks can form fractured rock aquifers if they contain sufficient secondary fractures. The fractures make up an interlocking network to transmit water but are independent of rock type and therefore difficult to predict. If the fractures are relatively planar and parallel or subparallel, they form joints. Fractures and joints can be tens of yards long and have apertures up to 0.25 inch (5 mm) or more. In terms of water flow, these joints and fractures act more as pipes than typical porous aquifers. Groundwater infiltrating joints and fractures make minimal contact with the rocks, reducing the chemical reactions and thus the purification. The apertures of the joints and fractures are so large that microorganisms and particulate are not removed. They effectively function as water pipes do in a house. For these reasons, groundwater in crystalline rocks tends to be of lower quality and very sensitive to human activity, both on the surface and underground. If the density of the joints and fractures is high, then drilling for water in crystalline rocks yields similar results to drilling in sediments and sedimentary rocks with potentially even

higher yields. Zones of very high fracture density are fracture zones or fracture trends. If the joint and fracture density is low, the odds of intersecting them with a drilled water well decrease significantly, and wells may have to be drilled very deep before they encounter producible water. The inconsistent nature of joints and fractures means that one house may be able to produce water from a shallow well and the next-door neighbors might have to drill deep wells for their water.

Any area underlain by crystalline rock will produce water from fractured rock aquifers or not at all. Many areas of the United States are underlain by crystalline rock. Along the East Coast, the entire Piedmont Province except the Mesozoic basins (Hartford, Newark, Gettysburg, Taylorsville, Richmond, Dan River, etc.) and the entire Green Mountains, Highlands Province, and Blue Ridge Mountains are crystalline rocks and rely on fractured rock aquifers. This means that the cities of Boston, New York, Philadelphia, Baltimore, Washington, D.C., and Atlanta, among others, are all underlain by crystalline rock and fractured rock aquifers. The Northeast also has glacial deposits over the crystalline rock, forming a complex double aquifer system in many cases. Crystalline rocks are also present where the Canadian shield juts into the United States across northern Michigan, Wisconsin, and Minnesota, but they have glacial cover there as well. From the Rocky Mountain front westward, there is a complex interlayering and interfingering of crystalline rocks and sediments. In the Basin and Range Province, much of the range area is crystalline, whereas much of the basin area is sediment. Other very large crystalline rock areas include the Sierra Nevada of California, the Columbia River and Snake River plateau of Washington, the Colorado plateau, the Llano uplift of Texas, the Arbuckle Mountains of Oklahoma, and the Adirondack Mountains of New York.

### KARST AQUIFERS

Limestone erodes to form karst aquifers, geologic formations that yield usable quantities of water. Acidic surface and groundwater infiltrates fractures in the limestone and dissolves the rock around it. With time, cave systems form and transmit groundwater in huge underground rivers. These caves act as larger pipes than fractured rock reservoirs and as such are less effective at purifying water. Virtually all surface water quickly drains into the caves, so rivers are few and small. In areas where the water table is shallow, sinkholes on the surface may appear as small circular ponds and lakes. The surface of these lakes is the water table.

**Block diagram showing how fracture systems produce water in wells**

Karst aquifers are the most environmentally sensitive type of aquifer. Sinkholes have opened up under railroad tracks, swallowing entire freight trains, and, in the early 1980s, a section of Interstate Route 10 in Florida collapsed into a sinkhole at night, and several cars plunged in before the state police closed the road. There is even a story from Egypt that some chickens fell into a well in a karst aquifer only to climb out of another well about a mile away. Not only can karst aquifers transport cars and chickens, they can just as efficiently transport pollutants in far greater quantities than any other groundwater system. In one case, a whole football field-sized industrial waste lagoon disappeared overnight into a sinkhole along the Delaware River, New Jersey, liner and all. With examples like these, it is readily apparent why it is so important that landfills, waste storage facilities, and chemical holding tanks, among others, not be located in karst regions.

Karst systems can be anywhere that there is limestone, but they are far more prevalent in areas of adequate rainfall or extensive groundwater systems. Probably the most famous karst aquifer is the Floridan Aquifer of Florida, Georgia, and Alabama. It underlies virtually the entire state of Florida and is the site of an immense struggle between the agricultural and industrial growth and those who want to preserve the quality of their drinking water. Karst aquifers cover a huge area of the eastern central part of the United States from New York through Ohio, Illinois, and Michigan; southward through West Virginia, Kentucky, and Tennessee; and into parts of other states to the south. The Edwards Aquifer of Texas is also a karst aquifer and has the highest recorded flow rates ever measured in the United States. It, too, struggles with pollution and damage to fragile ecosystems.

### PERCHED AQUIFERS

A perched aquifer is one that sits encased in aquiclude at a higher elevation than the main aquifer for an area. Perched aquifers usually require unusual depositional situations and are most common in glacialized terrenes. Kame deposits (a ridge or mound of sand and gravel deposited by melting glacial ice) in glacial lakes consist of sediments with high porosity and permeability encased within the impermeable clays of the lake deposits. Kame deltas at the various levels during shifting of glacial lake levels also produce clay-encased sands and gravels. Even the scraped bowl-shaped depressions in crystalline rocks may later be filled with sediments that are totally cut off from the main groundwater system. Besides glacial processes, progressive erosion may remove an aquifer from above an aquiclude layer but leave part of it in an elevated position.

Perched aquifers tend to contain small amounts of water, which may dry up during droughts or if they are drained by wells. Their small size enables them to be polluted readily. On the other hand, because they are isolated, the pollution cannot easily escape into the main groundwater system. Love Canal, New York, was in actuality an artificial perched aquifer that contained a large quantity of industrial waste. It was contained in glacial clays and would not have been a problem if homes and a school had not been built directly on top of the waste facility.

**Argo Merchant oil spill Georges Bank, New England (December 15, 1976) Water Pollution** A shoal is a relatively shallow area of seafloor that can be a hazard to navigation. If a shoal is hundreds of square miles in area, essentially forming an upland on the seafloor topography (bathymetry),

**Illustrations showing the relationship between textural features and porosity/permeability in sediments. Equigranular rounded grains show good porosity and permeability (A); grain sizes show greatly reduced porosity because the small grains fill the pore spaces (B); mineral cement coating the pores preserves most of the porosity but reduces or eliminates the permeability (C).**

it is called a bank. Several banks are found between Newfoundland, Canada, and southern New England. The series of banks to the north are collectively called the Grand Banks. To the south, off Massachusetts, is Georges Bank, perhaps the most well known of the shoals on the U.S. continental shelf. Georges Bank is a 150-mile- (250-km-) long by 78-mile- (130-km-) wide, roughly circular, submerged plateau that rises more than 390 feet (120 m) above the ocean bottom. It is a remnant of the last ice age and was once connected to the New England mainland. As sea level rose during deglaciation, this low-lying, sandy area first became an isolated coastal island and then was submerged and eventually inundated by the Atlantic Ocean.

Georges Bank is very valuable as a fishery. Driven by ocean water currents originating in Labrador, nutrient-rich seawater rushes southward in a clockwise motion across the bank and combines with warmer water from the Gulf Stream moving northward. Sunlight creates optimal conditions for the growth of phytoplankton (photosynthetic algae) and zooplankton (e.g., foraminifera and krill) in the well-oxygenated waters. These tiny, often microscopic life-forms make up the base of the oceanic food web and offer rich feeding grounds for cod, haddock, yellowtail flounder, and the fish that feed on them. More than 120 species of fish are found in Georges Bank along with numerous types of marine birds, whales, dolphins, and porpoises. Georges Bank has been fished commercially for almost 1,000 years.

### HISTORY OF THE SHIP

The tanker *Argo Merchant* was built in 1953 in Hamburg, Germany. The ship had an operational history plagued with mechanical problems, collisions, groundings, and a near-sinking. Originally christened the *Arcturus*, it was 640 feet (197 m) long, had a beam (width) of 84 feet (26 m), and displaced almost 19,000 tons (17,273 metric tons). With a single steel hull that extended 34 feet (10.5 m) below water, the *Argo Merchant* could travel at 16 knots (29.6 km/h) and carry almost 8 million gallons (32 million L) of oil. Its first 10 years were uneventful, but starting in 1964, the *Argo Merchant*'s machinery and engines began to break down. Over the next 10 years, it was involved in more than a dozen incidents.

In 1967, during a voyage from Japan to the United States, the *Argo Merchant* collided with a Japanese ship, caught fire three times, and had to stop for repairs five times. A journey that only should have taken several weeks lasted more than eight months. This was followed by a mutiny in 1968, the crew

rioting over dangerous working conditions, poor food, and unpaid wages. It went aground off Borneo in 1969, and, in 1976, the boilers failed to operate and the steering mechanism broke down, causing the captain to post warning lights alerting other ships that the *Argo Merchant* was out of control. The ports of Boston and Philadelphia refused to let it dock, and the *Argo Merchant* was even forbidden to pass through the Panama Canal. Sold and renamed several times (*Permina Samudra III* and *Vari*), the ship was purchased in 1973 by a start-up company called Thebes Shipping, Inc., renamed the *Argo Merchant*, and, by 1975, had such a bad reputation that the U.S. Coast Guard tried to prevent it from entering U.S. waters but could not legally enforce such a restriction at that time.

### THE ACCIDENT AND OIL SPILL

In early December 1976, the *Argo Merchant* took on a full load (7.7 million gallons, or 29.2 million L) of No. 6 fuel oil from a refinery at Puerto La Cruz, Venezuela. This fuel oil is a type of liquid petroleum, also called Bunker C, because it often is used as the primary fuel oil for ships and is stored in onboard fuel tanks called bunkers. It is a viscous (thick) oil that flows very slowly at room temperature. In order to be pumped or moved from one tank to another or from a tank to a furnace, No. 6 needs to be heated. Large steam or electric coils that are inside the tank or vessel where the oil is stored usually do this. The cargo of the *Argo Merchant* was destined for the industrial boilers of New England and was needed to keep furnaces fired through the long, cold Massachusetts winter.

As the *Argo Merchant* sailed northward along the east coast of the United States from Venezuela, problems arose. Flying a Liberian flag and under the command of a Greek captain, the *Argo Merchant*'s crew was struggling to keep the ship on course. The gyrocompass was not working, and the radio-direction finder could not be calibrated properly. In addition, neither of the two helmsmen held the necessary ratings to pilot a ship of this class, and the coastal charts that showed harbors and water depths were missing. As the evening of December 15, 1976, came on, the crew tried to navigate using the stars, but the weather closed in, and soon clouds obscured the sky, the seas started running high with 10-foot (3.3-m) waves, and gale force winds drove a blinding snowstorm. At approximately 6:00 p.m., the *Argo Merchant* ran aground on one of the most well-known and charted shoals along the East Coast, the Middle Rip Shoal of Georges Bank, some 20 miles (33 km) southeast of Nantucket Island. At the time

The oil tanker *Argo Merchant* ran aground and later leaked oil on the Georges Banks off the coast of Massachusetts on December 15–21, 1976. (NOAA)

of the grounding, the *Argo Merchant* was almost 25 miles (42 km) off course.

Although the crew worked through the night to refloat the ship and save its cargo, the engine room pumps could not keep pace with the water entering through a tear in the hull. At 7:00 A.M. the next day, the U.S. Coast Guard received a distress call from the *Argo Merchant* and responded almost immediately. After all, the ship ran aground only 50 miles (83 km) from the Coast Guard's main base in Woods Hole, Massachusetts. Arriving with oil containment booms, skimmers, and dispersants, the Coast Guard could only watch in frustration over the next five days as the rough seas and high winds prevented deployment of any oil recovery equipment. Indeed, the crew was lucky to be evacuated by helicopter just before the vessel split in two and sank on December 21, with the full cargo released into the ocean, on the southern edge of Georges Bank.

An oil slick 60 miles (100 km) wide by 100 miles (160 km) long quickly formed. The wreck of the *Argo Merchant*, and the discharge of almost 8 million gallons (32 million L) of Bunker C into the water just off Cape Cod, would become known as

the largest oil spill ever to occur from a marine vessel in the United States until the *Exxon Valdez* disaster in 1989, when 11 million gallons (43 million L) were spilled into Prince William Sound in Alaska.

### ECOLOGICAL EFFECTS AND AFTERMATH

Throughout most of its operational life, the *Argo Merchant* had earned a reputation as a “hard luck” ship, seeming to develop one problem after another and barely making the money needed to keep it afloat. The one piece of luck was that when she ran aground and sank in the stormy waters of the mid-Atlantic, she produced very few short- or long-term ecological effects. The no. 6 oil that the *Argo Merchant* was carrying was constantly heated by steam from the ship's engines. When the ship ran aground and cold ocean water flooded the engines, the oil began to congeal and harden. Although still fluid enough to escape the broken-up ship, the oil tended to sink to the middle of the shallow water column. It did not coat the bottom sediments of the shoal, nor did much of it wash up on the nearby beaches of Nantucket or Martha's Vineyard. Once in the water

column, it began to degrade physically, emulsifying or mixing with ocean water, and biologically under the influence of bacteria and other microorganisms eager to utilize the abundant carbon for their metabolic processes. The stormy weather with strong northwesterly winds pushed much of the oil out to the open sea and away from beaches and fishing grounds. It also was fortunate that the spill took place in mid-December, well into the Massachusetts winter, when biological activity is at very low levels. Most fish and other related aquatic life had moved southward to warmer waters and local fisheries were fairly inactive.

Within a few days of the accident, scientists studying the potential effects of the release noted that petroleum hydrocarbon levels in seawater samples near the wreck were 250 parts per billion (ppb), which are relatively low so near to the source of oil. These concentrations probably decreased further as the rough seas continued to mix and disperse the heavy oil. In 1977, sediment samples collected from shoals where the *Argo Merchant* had run aground did not contain high levels of hydrocarbon contaminants that could be related to the wreck. Today, it is generally thought that the spill had no lasting impact on local ecology.

**arsenic** The classic poison in history, literature, and plays, arsenic can also be an environmental hazard from both natural and anthropogenic sources. Despite arsenic's well-deserved reputation as a poison, more than 60 million Americans have dangerous concentrations of arsenic in their drink-

ing water, for the most part from natural sources. The states with the greatest incidence of arsenic poisoning are Michigan, Wisconsin, Minnesota, North Dakota, and South Dakota. It is even more prevalent in some other countries. It is estimated that in Bangladesh, which has a serious arsenic problem, some 200,000–270,000 people will die of arsenic-induced cancer alone. Other countries that have a high concentration of arsenic in drinking water include Argentina, Australia, Chile, China, Hungary, India, Mexico, Peru, and Thailand. In Bangladesh, China, and India, arsenic in drinking water has caused significant adverse health effects. In the United States, arsenic is considered to be the most dangerous pollutant on the 2007 CERCLA Priority List of the 275 most Hazardous Substances. It has been identified in 784 of the first 1,662 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List), indicating that it is quite widespread.

### SOURCES, USES, AND PRODUCTION

Arsenic is a semimetallic inorganic pollutant primarily from natural sources where the dissolution of rocks such as shale and slate; minerals such as arsenopyrite, realgar, and orpiment; and iron and manganese ores can introduce it into the natural environment. About one-third of atmospheric arsenic is the result of volcanic activity and low-temperature evaporation. Arsenic also can have industrial sources such as wood preservatives, alloying agents, pesticides, mining operations, glass manufacturing, and fossil fuel-burning plants. In 1996, the world leader in arsenic consumption was the United States, which used 24,400 tons (22,000 metric tons). It is estimated that some 70 percent of the world's arsenic production is used for copper chrome arsenate to treat wood (90 percent in the United States), 22 percent is used for agricultural chemicals, and the rest has various uses including paints, dyes, medicine, metal additives, and semiconductors. By 2007, consumption in the United States had decreased to 4,950 tons (4,500 metric tons), mainly as the result of environmental concerns. In 1998, the top industry in the world to deal with arsenic waste was metal mining with 309 million pounds (280 million kg) or 96 percent of the total. Gold mining accounted for 93 percent of the arsenic mine waste. Metal smelting (especially copper) and coal burning add most of the rest.

### ENVIRONMENTAL RELEASE AND CONSEQUENCES

Arsenic can be a point source pollutant from industrial discharge, leaks, or spills or a nonpoint source

pollutant from most natural sources and fallout. It can be found in lakes, rivers, or groundwater systems as the result of washout in rain or snow or through the discharge of industrial wastewater and dumping. Some arsenic sticks to particles in the water and settles to the sediment on the bottom of lakes or rivers, whereas some is carried along by the water. Ultimately, most arsenic ends up in the soil or sediment, where it can be tightly bound. Microbial action and chemical reactions may convert it into a less dangerous form.

An organic form of arsenic is also commonly ingested in low quantities primarily from seafood. This exposure is not considered to be a health threat to humans. Organic arsenic is also used extensively as an additive in poultry and hog feed and ultimately concentrates in animal wastes. It is uncertain whether this source of arsenic in the environment causes health problems directly or whether it can react to form a pollutant. In the past, inorganic arsenic compounds were predominantly used as pesticides, primarily on cotton fields and in orchards, but that use is now prohibited. Nonetheless, it is reported by the EPA that more than 185,636,503 pounds (84,380,229 kg) of arsenic and arsenic compounds were released into the environment by industry.

Arsenic is just as deadly to aquatic life, land animals, and birds as it is to humans. In soil, it has been shown to reduce crop yield, and some plants can take up arsenic. It is very persistent in the environment and is generally insoluble in elemental form. Some compounds, however, are highly soluble, and these can be readily transported from air or soil into the surface water and groundwater systems. Arsenic can bioaccumulate in aquatic and marine animals, but it is almost exclusively in the organic form, which is not nearly as dangerous. Removal of arsenic from water is typically accomplished by using coprecipitation of iron minerals by oxidation and subsequent filtration. Certain microbes may also convert arsenic into less dangerous compounds through bioremediation.

### HEALTH EFFECTS FROM EXPOSURE

Ingestion of a single large dose of the soluble inorganic variety of arsenic as well as arsine gas is acutely toxic to humans. More than 90 percent of arsenic is absorbed in the digestive tract, where it can cause gastrointestinal problems such as nausea, vomiting, abdominal pain, and hemorrhaging. Additional symptoms are renal failure, cardiovascular effects such as low blood pressure and circulatory collapse, and nervous system effects such as headache, muscular weakness, convulsions, and coma

possibly leading to death. These occur within one to 12 hours of ingestion. Even if the person survives, he or she can suffer from bone marrow depression, hemolysis, hepatomegaly, melanosis, polyneuropathy, and encephalopathy. Chronic exposure can result in muscle cramping, diarrhea, anemia and other blood problems, high blood pressure, cardiac arrhythmia, congestive heart failure, irreversible sensory and motor polyneuritis, endocrine problems (diabetes), bile duct enlargement, and immune deficiencies. Arsenic exposure to the skin can also cause dark skin blotches (hyperkeratosis) and warts on the palms, feet, and upper body. In rare instances, it can cause blackfoot disease, which is a severe form of peripheral vascular disease that can lead to gangrene. In pregnancy, arsenic can pass through the placenta and enter the fetus, causing spontaneous abortions, high male-to-female birth ratios, and low birth weights.

Chronic arsenic exposure at the environmental level over a period of 10 years or more has been documented to cause cancer. Arsenic in drinking water has been shown to result in skin and lung cancer, and it is strongly implicated in cancer of the nasal passages, colon, bladder, prostate, and kidneys. Some studies claim that tobacco can contain as much as 6 micrograms of arsenic in a pack of cigarettes, whereas others claim that cigarette smoke simply exacerbates the effect of arsenic on the lungs and promotes cancer.

### REGULATIONS ON HUMAN EXPOSURE

As a result of the severe adverse health effects and widespread distribution, federal agencies have placed regulations on human exposure to arsenic. The EPA revised limits on arsenic in drinking water from 50 to 10 parts per billion (ppb) on February 22, 2002 (the Arsenic Rule). By January 23, 2006, all public water supplies that serve 15 locations and/or 25 residents on a year-round basis were required to meet this criterion. The new standard required corrective action for 3,000 of the roughly 54,000 community water systems, improving the water supplies for more than 13 million people. Private wells in designated "hot spot" geographic regions should also be tested. The Occupational Safety and Health Administration (OSHA) set a permissible exposure limit (PEL) of 10 micrograms per cubic meter of air for airborne arsenic in various workplaces that use inorganic arsenic over an eight-hour-workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) set a designation of immediately dangerous to life and health (IDLH) of 5 mg/m<sup>3</sup> of workplace air.

**asbestos** Asbestos is a shortening of the term *asbestiform mineral* and therefore describes the form of a mineral rather than its composition. Any one of a number of naturally occurring minerals can form asbestos through the addition of water to their crystalline structures. Asbestos must have an extreme aspect ratio (a width-to-height ratio of 20–1,000) and be acicular (needlelike) in form. The most common asbestos is *chrysotile*, or *white asbestos*, which is a mineral in the serpentine group (silicates of magnesium, iron, aluminum, nickel, zinc, and manganese). It has a rolled structure, appearing as a minute straw under an electron microscope but as bundled soft friable fibers to the naked eye. It is less stable than the other types of asbestos but still degrades slowly when exposed to weather or in the lungs. *Blue asbestos* is the mineral crocidolite, which is a variety of riebeckite, a member of the amphibole group (hydrous silicate with iron, magnesium, and other elements). It may also occur as bundles of soft friable

fibers or straight, stiffer bladelike fibers. Amphiboles are much more resistant to degradation and can persist for long periods in the lungs. *Brown asbestos* is another type of amphibole, called grunerite, but sold under the trade name Amosite, an acronym of Asbestos Mines of South Africa. Other recognized asbestos minerals include tremolite, actinolite, and anthophyllite, all of which are amphiboles but none of which is common. Other fibrous minerals such as rutile and apatite have been proposed to be classified as asbestos, but they have not been designated as such to date. Asbestos is rated as the 90th worst pollutant on the 2007 CERCLA Priority List of Hazardous Substances, and it has been identified in at least 83 of the first 1,585 U.S. Environmental Protection Agency (EPA)–designated Superfund sites.

#### PROPERTIES, USES, AND PRODUCTION

For millennia, asbestos has had a variety of applications, with its earliest documented use in 2500 B.C.E. in Finland. In ancient times, it was greatly valued as a "miracle mineral" and employed extensively in everything from lamp wicks to fireproof cloth and insulation, as it was incorporated into until very recently. The most common use for chrysotile asbestos in recent times has been in brake linings for cars, pipe insulation, floor and ceiling tiles, plasters and stuccos, fire-proofing, and house shingles. It also has been used extensively in less common items such as fire blankets, clutch plates, gaskets, caulk, sheetrock tape, some types of house insulation, texture coats and "transite" composite panels, siding, and countertops. Amphibole asbestos is typically applied as insulation for ceiling tiles, fire doors, and gaskets and in asbestos cement sheets and pipes and casing for water and electrical conduits. In many cases, the two types are mixed together for common applications. Probably the most notorious use for asbestos was as a coating for ships. In shipyards, millions of tons of finely ground asbestos were sprayed onto the hulls of ships by large numbers of naval shipbuilders, who, for years, worked in large clouds of asbestos.

The majority of minable asbestos deposits occur in serpentinite rock bodies. Serpentinite results from the alteration and low-temperature metamorphism of an ultramafic body (rocks without much silica and high concentrations of iron and magnesium) such as peridotite under proper conditions. Several serpentinites are present in populated areas such as Staten Island in New York City and near Baltimore, Maryland, and may pose threats as asbestiform minerals are released during excavation and road or building construction on or near the rock bodies. The most productive (and earliest) mined serpen-

Royal Air Force trainees wearing asbestos suits walk through petrol fires in England, November 1941. (© Hulton-Deutsch Collection/CORBIS)

tinite in the East is the Thetford area of Quebec, Canada, in 1878. Other sizable asbestos deposits occur in calc-silicate metamorphic rocks. On an international level, the largest producer of asbestos is Russia with more than 1.18 million tons (925,000 metric tons) produced per year (39 percent of total) in 2006. The peak production of asbestos was in 1977, when it reached 2.4 million tons (2.2 million metric tons), but it has decreased steadily in response to the health concerns. The United States ended its domestic production in 2002, and imports have continued to decline from 7,700 tons (7,000 metric tons) in 2002 to 715 tons (ca. 650 metric tons) in 2009.

### ENVIRONMENTAL RELEASE AND CONSEQUENCES

In natural settings, asbestos is not generally a health risk. The fibers tend to be long and bundled with no risk of inhalation. Asbestos, however, is easily disaggregated and, if ground, forms small 3.0–20.0

by 0.01-micron fibers that are easily made airborne and can float as dust for long period. Asbestos is therefore readily inhaled into the lungs. The sharp fibers can become lodged in lung tissue and cause irritation. Even if just moistened, the size and shape of asbestos fibers make them readily adhere to the lungs and very hard to expel. Asbestos fibers in the lungs can cause a variety of diseases. More than 10,495,930 pounds (4,770,877 kg) of asbestos were reported to have been released into the environment from various manufacturing operations in 2005. In most cases, it is a point source pollutant from a specific building, but it is so prevalent, much can be considered a nonpoint source pollutant because the source cannot be identified.

### HEALTH EFFECTS FROM EXPOSURE

It is estimated that some 9,900 people die of asbestos-related diseases per year. The main asbestos disease is asbestosis, which was first identified in naval

shipbuilders. The numerous fibers of asbestos that become lodged in the lungs cause scarring of the lung tissue not by direct irritation, but by acid produced by the lungs to rid themselves of the asbestos. Eventually, the scarring may become severe to the point that the lungs no longer function and the person suffocates. The time frame between exposure to the onset of advanced disease is on the order of 10–20 years. Asbestosis can be caused by any variety of asbestos but is mainly caused by chrysotile. The second main and probably more notorious asbestos disease is the cancer mesothelioma, which primarily affects the mesothelial lining of the lungs as well as the chest cavity, the abdominal cavity, and/or the sac surrounding the heart. There is evidence that at least 50 percent of malignant mesothelioma is related to asbestos exposure; however, the lapse in time between exposure and occurrence is 35–45 years. The survival time for patients with advanced mesothelioma once it is diagnosed is 11 months. Smokers have a much higher rate of mesothelioma, indicating that tobacco works synergistically with asbestos to cause cancer. The current thinking is that mesothelioma is caused by reactive oxygen species in the lungs as the result of exposure to asbestos with the possible participation of the simian virus 40. Mesothelioma is believed to be more commonly caused by exposure to amphibole varieties of asbestos and especially crocidolite. There are also some nonmesothelioma forms of cancer that appear to be related to asbestos either in air or in water. They include cancer of the larynx, pharynx, stomach, and colorectal region.

### REGULATION ON HUMAN EXPOSURE

Asbestos occurs in both air and water, although it is far more dangerous in air. In nature, asbestos exists in long fibers and bundles; it is the grinding of asbestos for industrial uses that converts it into a killer. The Occupational Safety and Health Administration (OSHA) established a long-term industrial air limit of 100,000 fibers per cubic meter of 5 micrometers or greater (roughly 0.1 fiber per cubic centimeter) for eight-hour shifts and 40-hour workweeks. The short-term exposure limit (STEL) is one fiber per cubic centimeter averaged more than 30 minutes. The EPA set a limit of 7 million fibers per liter of drinking water. In school and residential settings, no asbestos in the air is considered the goal of most cleanup or abatement activities, although it is readily recognized that complete removal of asbestos from the environment is unobtainable because of its widespread presence from both natural and anthropogenic sources.

OSHA has established four classes of hazards in asbestos work and activities. Class I is the most hazardous classification and covers the removal of thermal system insulation and sprayed or troweled-on surface materials that contain or are presumed to contain asbestos. Class II is the second most hazardous and covers removal of other types of materials that contain asbestos, including resilient flooring, home siding, and roofing materials. Class III covers repair and maintenance operations in areas where materials are disturbed that are documented or presumed to contain asbestos. Class IV is for custodial activities dealing with waste and debris that contains asbestos. There are certain regulations that must be adhered to for work with asbestos. The work area must be separated (usually using plastic sheets) as regulated areas in which eating, drinking, smoking, chewing gum or tobacco, and application of cosmetics are prohibited. Workers must be fully covered in a protective suit including gloves and goggles and must wear a respirator that is certified for asbestos work. In areas where class I and class II workers are exposed to asbestos levels exceeding the permissible exposure limit (PEL), daily monitoring of workers is required.

### ASBESTOS IN BUILDINGS

After asbestos was recognized as a health threat, efforts were made to remove it from all buildings and dispose of it. The problem is that asbestos has been used in more than 5,000 products and as such is very widespread. On average, homes, schools, and other buildings have 30 to 6,000 fibers per cubic meter, and even outside air in rural areas averages 10 fibers per cubic meter. Near an asbestos factory or mine, the concentration typically exceeds 10,000 fibers per cubic meter. Literally everyone has these ubiquitous and tiny asbestos fibers in his or her lungs; it just depends on the number and type of fibers, the condition of the lungs, heredity, and other factors as to whether health problems will ensue. The process of removing asbestos from a building was found actually to increase the amount of asbestos in the air for up to two years after the remediation is complete by stirring up the tiny fibers. Exposure levels actually increased in many cases. As a result, new legislation allowing encapsulation of asbestos-bearing material has been passed in many areas, and many have questioned the practice of removing it at all.

The dangers of asbestos have been known for many years, and, as a result, many minerals that are structurally or chemically similar to asbestos have also come under scrutiny over time. Talcum

powder has been potentially found to contain asbestos, as the mineral talc is typically associated with serpentine. If water is incorporated into the crystallographic structure of serpentine, asbestiform minerals are created. Houses insulated with vermiculite have also been scrutinized. Vermiculite is a naturally occurring mica mineral that greatly expands into puffed, wormlike pieces with useful thermal insulating capacity. Asbestos minerals are commonly associated with vermiculite, and industrial facilities that process vermiculite into insulation have high air concentrations of asbestos. It is also used as packing material and in garden products. Lime quarries and subsequently lime for lawns have also been found to be potential sources of asbestos. The amphibole tremolite has been found in asbestos form in several lime quarries in metamorphic rocks, and, as a result, several have been shut down.

Asbestos litigation has become the most expensive of all environmental legal cases, with more than 600,000 claimants and 6,000 defendants. This trend will probably continue into at least the next decade as more asbestos workers and handlers begin to develop asbestos-related diseases. It is estimated that the cost of asbestos litigation will eventually reach \$200 billion, even with limits on claims of the many class-action lawsuits.

**Atlantic Empress oil spill Tobago (July 19, 1979) Water Pollution** On July 19, 1979, the weather was severe off the coast of the island of Tobago, in the southern Caribbean Sea. Storms with heavy rain squalls were predicted throughout the night. The two VLCCs (very large crude carriers), "supertankers" used for the transport of liquid fuels weighing more than 182,000 tons (200,000 metric tons), that were in the area that night hardly seemed to notice as they plowed through the dark waters toward their respective destinations. These vessels were enormous, each more than 1,000 feet (454 m) long and less than 12 years old. They were equipped with the most modern navigational equipment available, including radar and radio-direction finders. Both had well-trained crews with good safety records.

Bound for Singapore, the *Aegean Captain* was carrying approximately 1.4 million barrels (59 million gallons, or 269 million L) of Venezuelan refined petroleum from storage tanks in Aruba and Bonaire in the Lesser Antilles. The five-year-old *Atlantic Empress* was carrying 1.9 million barrels (80 million gallons, or 364 million L) of unrefined Saudi Arabian crude oil that had been purchased by Mobil Oil Corporation. The *Aegean Captain* was Greek owned and flew a Liberian "flag of convenience," which is an international registry system sometimes used by shipowners to avoid taxes, labor laws, and more stringent safety requirements than in countries where they may actually be based such as the United States or those in Western Europe. Other countries commonly used as flags of convenience include Panama, Cambodia, and Bolivia, which has no coastline.

## THE ACCIDENT AND OIL SPILL

At approximately 8:00 P.M., these two huge ships collided in a rainstorm about 20 miles (32 km) east of the Tobago coastline. Although the cause of the accident has never been definitively determined, crewmen on deck first raised the alarm when they peered through the fog and rain of a thunderstorm and realized they were only 600 yards (554 m) apart and closing fast. The *Aegean Captain* overtook and smashed into the

The oil tanker *Atlantic Empress* on fire near Trinidad and Tobago, after colliding with another tanker, July 21, 1979 (© UPI/CORBIS)

stern of the *Atlantic Empress*, and both ships burst into flame upon impact, with the *Atlantic Empress* receiving the most damage.

A hole was torn in the *Aegean Captain's* starboard bow and the forward deck erupted into flames, but the crew of 35, assisted by an international team of salvage and firefighting experts, had the conflagration under control and extinguished within 48 hours. One sailor on the *Aegean Captain* lost his life as a result of the collision. The *Aegean Captain* proceeded, partially under its own power, to an anchorage 10 miles (16 km) off the coast of Trinidad for inspection by government officials. The tanker then was towed into port at Curacao, where the cargo was unloaded. During the fires and post-collision maneuvers, the *Aegean Captain* was estimated to have lost approximately 100,000 barrels of oil (about 7 percent), most of which was treated through the use of dispersants during subsequent salvage and towing operations. The *Aegean Captain* was repaired and returned to service within a few months of the collision. The *Atlantic Empress* was not so fortunate.

The collision ripped open a rear fuel compartment, or bunker, on the *Atlantic Empress* and burning oil spilled across the stern decks and into the ocean. Flames leaped more than 100 feet (31 m) into the night air, and a wake of burning oil extended more than 200 yards (185 m) behind the ship. Later, an explosion in one of the ship's center tanks increased the flow of oil into the sea and spread the fires across most of the ship. Eventually the slick from the *Atlantic Empress* covered 10 square miles (25.6 km<sup>2</sup>). Six oceangoing tugboats quickly converged on the scene of the collision and tried to assist the crew of the *Atlantic Empress* in extinguishing the fires and in trying to salvage the ship and her cargo.

Two tugboats managed to attach towlines to the *Atlantic Empress* and drag her farther out to sea, away from more ecologically sensitive shorelines and bird nesting areas. In all, 26 died in the explosion and fire out of a crew of 37 and three passengers. Included in the dead was the radio operator, who remained onboard with the captain to coordinate salvage operations after the rest of the crew and passengers were airlifted from the vessel. Five of

the survivors were hospitalized with severe injuries, including burns. The captain, the last one to leave the vessel, was badly burned after running through a wall of fire to reach rescuers waiting to take him off the ship.

The fires burned for another two weeks until, 15 days after the collision on August 2, 1979, the tanker began to list badly to port and the towropes had to be released. The *Atlantic Empress* sank in several hundred feet of water in the Caribbean Sea, taking with her almost all of the cargo of crude oil.

### ECOLOGICAL AND ECONOMIC IMPACT

The immediate ecological impacts of the collision were relatively minor. Soot from the fires temporarily contaminated drinking water reservoirs in several coastal communities in Tobago. The oil slick from the collision and fires, however, did not reach land, evaporating and dispersing in the sea after being saturated with dispersant from tugs and cleanup vessels. There were no recorded fish or bird kills as a result of this disaster. The *Atlantic Empress* spill, however, occurred at a time when environmental concerns were secondary to those relating to economic impacts, namely, the value of the lost ship and oil. No long-term studies were ever done as to potential ecological consequences of the spill by the government of Tobago, ship's owners, or insurers.

The collision and loss of the *Atlantic Empress* had significant financial implications. Insured by Lloyd's of London, the ship and her cargo of 275,000 tons (250,000 metric tons) of crude oil were valued at \$85 million. This turned out to be the largest financial loss to Lloyd's up to that time, and certainly the largest loss related to a single commercial vessel.

Lloyd's of London is not a business or corporation, but a marketplace where British insurers meet to share the risks and rewards of the commercial insurance coverage they sell collectively. Lloyd's began at a coffee shop owned by Edward Lloyd on the Thames River waterfront. By 1688, businessmen and insurers would meet there to set down the details of the insurance policies for vessel and cargo, signing their names at the bottom of the agreement alongside the amount to which they were committed. This practice of "underwriting" the policy continued even after Lloyd's death, when the process became more formalized and was moved to the Royal Exchange building as the Society of Lloyd's. By the early 1900s, Lloyd's had become the premier insurer in the world, with participants made up of both corporations and individuals.

When a merchant or ship's owner sought insurance, Lloyd's corporate members would form a syndicate designed to insure against specific risks. The members of the syndicate are pledged to reimburse any loss "down to their last collar stud," which is meant to include their own personal fortunes and possessions. In the early days of Lloyd's, it was not uncommon for unskilled underwriters to lose everything when a ship sank or a building burned.

Without affordable insurance, no shipowner or merchant would be willing to accept a cargo for delivery or contract for the movement of oil. The *Atlantic Empress* claim sent shudders through the merchant shipping industry as premiums rose across the board and insurers began to take a much more active role in how tankers were built, maintained, and operated.

**atrazine** In a few cases, contaminants can be removed from use and then reinstated. The strong herbicide atrazine had been classified by the U.S. Environmental Protection Agency (EPA) as a Restricted Use Pesticide (RUP) since 1993, but in 2006 most of the restrictions were removed and it was reregistered. Prior to 1993, it was one of the most widely used herbicides in the United States for several years. For example, from 1987 to 1989, it was the most heavily

used herbicide in the country, applied to corn and soybeans in Illinois, Indiana, Iowa, Kansas, Missouri, Nebraska, Ohio, Texas, and Wisconsin. In 1990, it was applied to more than 64 million acres (26 million ha) of cropland. Trade names and synonyms for atrazine include Aatrex, Actinite PK, Akticon, Argezin, Atrazinax, Atranex, Atrataf, Atred, Candex, Cekuzina-T, Chromozin, Crisatrina, Cyazin, Fenamin, Fenatrol, Gesaprim, Griffex, Hungazin, Inakor, Pitezin, Primatol, Radazin, Simazat, Strazine, Vectal, Weedex A, Wonuk, Zeapos, and Zeazine. Even though atrazine is one of the more widespread contaminants, it occurs in relatively few EPA Superfund sites; thus far, it has been found in only 20 of the first 1,636 sites on the National Priorities List (NLP), where it was analyzed.

### PROPERTIES AND USE

Atrazine is a selective triazine herbicide that has been produced synthetically since 1959. It is an odorless white powder that dissolves in water and is not particularly volatile, reactive, or flammable. It has been used primarily to control the growth of broadleaf and grassy weeds in crops of corn, soybeans, sorghum, sugarcane, pineapple, macadamia orchards, asparagus, and roses, and in grasslands and rangelands, forests, turfgrass sod, conifer restoration plantings, noncropped industrial lands, and fallow lands. The advantages of atrazine are its potency, low cost, fit with soil-saving conservation tillage programs, low risk of crop injury, and versatility in application time—before or after crop emergence. It was for these reasons that it became so popular. Even while it was considered a restricted-use pesticide, the United States used 77 million pounds (35 million kg) of atrazine in 2003. It also has numerous industrial uses including in dyes and explosives.

### ENVIRONMENTAL RELEASE AND FATE

Atrazine is primarily a nonpoint source pollutant discharged as the result of agricultural uses and has only minor point source occurrences at production facilities from releases or spills at storage facilities or during transportation. It is far and away most commonly released to soil, where it is highly persistent. Atrazine breakdown is most commonly the result of microbial activity, which is enhanced by hydrolysis and faster at extremes in pH, especially under alkaline conditions. In dry or cold settings, it may persist for more than one year. It is moderately to highly mobile in soils with low clay or organic content, but it can be adsorbed onto clay-rich soils and colloidal materials. The high mobility means that it is likely to con-

taminate groundwater. Its lack of significant chemical breakdown and slow biodegradation in water make it highly persistent. As a result, atrazine is the second most common pesticide found in wells, both private and public. The states with the most common presence of atrazine in well water are Delaware, Illinois, Indiana, Iowa, Kansas, Michigan, Minnesota, Missouri, Nebraska, and New York. It is also common in surface water as the result of runoff from agricultural areas. Atrazine was found in high concentrations in all 146 water samples from locations along the Mississippi, Ohio, and Missouri Rivers and their tributaries in a U.S. Geological Survey study. Part of the 1993 restriction on atrazine was the requirement of a buffer zone between the application area and surface waters as a result of these occurrences. Even though evaporation of atrazine from surface water and soil is insignificant, it may still enter the atmosphere through industrial emissions and agricultural spraying. It is removed through reactions with hydroxyl radicals in air produced by photochemical reactions. Reported industrial release of atrazine was 504,187 pounds (229,176 kg) in 2005.

### TOXICITY AND HEALTH EFFECTS

Atrazine is classified as a class III, slightly toxic, substance. In acute exposures, symptoms include abdominal distress, diarrhea, vomiting, eye irritation, mucous membrane irritation, and skin irritation. At high doses, rats exhibit central nervous system effects such as excitation followed by depression and loss of coordination, accompanied by other effects including muscle spasms, labored breathing, prostration, convulsions, and death. Long-term chronic exposure to atrazine resulted in damage to the heart, lungs, liver, kidneys, ovaries, spleen, brain, and endocrine organs of laboratory animals. About 40 percent of the rats subjected to moderate doses of atrazine died within six months, exhibiting respiratory distress and paralysis of the limbs. In one study, atrazine caused an increase in incidence of mammary tumors in rats over a lifetime of exposure, but no other studies found a link to cancer. One group of researchers also reported that even in small doses, atrazine can be an endocrine disruptor, but the results could not be replicated in other laboratories, and the findings are not considered definitive.

### REGULATIONS ON HUMAN EXPOSURE

Certainly, during its history, atrazine has been subject to tremendous scrutiny, and regulations have been changed drastically. The EPA has set a drinking water

limit of three parts per billion (ppb) under the Safe Drinking Water Act. They have also set limits on contents in foods from 0.02 to 15 parts per million (ppm). The Occupational Safety and Health Administration (OSHA) regulates workplace air to a maximum of 5 milligrams of atrazine per cubic meter for an eight-hour-day, 40-hour workweek. It is unlikely that these standards will change during the reregistration.

# B

## **Bangladesh, arsenic in soil and ground-water Bangladesh (1970s–present) *Water Pollution***

The People's Republic of Bangladesh was established in 1972 after a bloody war of independence with Pakistan. Most of its land area is low-lying, 90 percent within 30 feet (9.1 m) of sea level, and wedged between India and Myanmar on the coast of the Bay of Bengal. The deltaic marshes and jungles that characterize much of the land have been created by soil and sediment deposited by the Ganges (Padma), Brahmaputra (Jamuna), and Meghna Rivers and their tributaries as they flow to the Bay of Bengal. Mild winters and hot humid summers dominate the seasonal climate, with June through October monsoons providing essentially all of the rainfall.

Bangladesh has a population of 147 million, making it the seventh most populous country in the world. Further, all these people occupy an area about the size of Wisconsin, making it one of the most densely populated places in the world. The average population density is 2,600 people per square mile (4,186 people per km<sup>2</sup>). For comparison's sake, the United States has a population density of about 80 people per square mile (129 people per km<sup>2</sup>).

Its alluvial soil is very fertile, filled with organic nutrients within transported sediments and irrigated by soaking monsoon rains. For this reason, farming is the principal occupation in Bangladesh and practiced by about two-thirds of the population. The average annual income is only about \$400, and the country is regularly struck by natural calamities such as droughts when the monsoons do not occur and floods when they do. Bangladesh has also been struck by some of the most deadly cyclones in history, including the 1970 cyclone, one of the worst natural disasters of the 20th century. Its lack

of strong political institutions; the mismanagement of its energy resources, particularly natural gas reserves; and a growing population have all contributed to make Bangladesh an undeveloped nation, with about one-third of its people living in poverty. Developed countries, the United Nations, and several nongovernmental organizations have long been involved in trying to improve economic and social conditions in Bangladesh. Outside aid makes up about 2 percent of Bangladesh's gross domestic product, and it is one of the largest recipients of United Nations resources.

### **ADVANCEMENTS IN PUBLIC HEALTH**

One of the first public health issues Bangladesh faced was the availability of clean drinking water. When it achieved independence in the early 1970s, most of the rural population relied on surface water sources (ponds, streams, and small creeks) as primary sources of drinking water. These surface water supplies proved to be susceptible to bacterial contamination by human and animal wastes. Outbreaks of cholera and dysentery killed 250,000 children every year. UNICEF (United Nations Children Fund, formerly United Nations International Children's Emergency Fund) sponsored a program to replace these surface water supplies with safer, more bacterially free groundwater sources. Almost 8 million tube wells were drilled into the shallow aquifer systems that underlie most of the central and southern parts of Bangladesh. A tube well, also called a driven well or drive point well, is one that is installed by pushing or hammering a perforated pipe or tube into the ground until it encounters a water-bearing zone. The well usually is four to six inches (10.2–15.2

cm) in diameter and less than 20 feet (6.1 m) deep. It can be installed manually, without the need for specialized drilling equipment, using a metal tripod, a pulley, and some weights. The perforated tube or pipe, which is made in five- or 10-foot (1.5- or 3.1-m) lengths, has a sharp, hardened tip. The pipe or tube is placed vertically underneath the tripod directly below the drive weights, which are attached by ropes to a pulley. The weights then are repeatedly raised and dropped onto a special metal drive head, and the pipe is driven into the ground. Additional lengths of pipe can be screwed into the top of the pipe as it advances through the ground. With favorable subsurface conditions, tube wells can be driven to a depth of more than 150 feet (45.7 m) below grade.

Once the bottom of the tube is at the correct depth, a small submersible pump is installed to draw the groundwater to the surface. In Bangladesh this pump, similar to pitcher pumps once so commonly seen throughout rural North America, operates on a treadle system. The person drawing the water simply steps onto the pedals and “walks in place” until water flows out of the spigot. Tube pumps and wells typically can be installed almost anywhere and for less than \$100.

These wells had an enormously beneficial impact on Bangladesh’s agricultural and public health systems. Irrigation became more reliable and less dependent on seasonal monsoons, and crop yields began to increase. The social impacts also were significant. With wells closer to their villages and farms, women no longer had to carry water long distances and could spend additional time on other, more important family-related activities. Infant mortality rates from water-borne diseases plummeted. One study estimated that more than 6 million tube wells were installed across the country in the late 1970s and early 1980s. By the late 1990s, more than 90 percent of the population was drinking groundwater provided by tube wells.

### RESULTING WATER QUALITY PROBLEM

Although the tube wells solved one problem, they introduced another. It would have been a wise decision for U.N. or government officials to have conducted widespread testing of groundwater quality before committing the country to using it for public consumption. Such studies would have shown that the Ganges (Padma), Brahmaputra (Jamuna), and Meghna Rivers and their tributaries flowed through the upland areas of Bangladesh and eroded rocks and sediments rich in sulfide and iron minerals. They liberated naturally occurring deposits of arsenic, which are often associated with these elements. The rivers that carried the fertile soil to Bangladesh

**Results of arsenic poisoning (“blackfoot disease”) on a Bangladeshi in Sonargon, Bangladesh, 2003** (Rafiqur Rahman/Reuters/Landov)

also carried in arsenic. Once deposited in deltas and floodplains, arsenic entered the groundwater as part of a reducing dissolution reaction with iron hydroxide, which increased the arsenic’s solubility.

If ingested at elevated concentrations, arsenic can have significant health effects ranging from wart-like skin lesions, called blackfoot disease, to central nervous system damage, cancer, and death. Although the World Health Organization (WHO) set an allowable limit of arsenic in drinking water at 10 parts per billion (ppb) and the U.S. Environmental Protection Agency (EPA) set the allowable maximal contaminant level for arsenic to 10 ppb, the Department of Environment in Bangladesh has established an arsenic limit of 50 ppb for drinking water, five times higher than the WHO’s EPA standards. The Bangladeshi government feels that public health protection needs to be balanced against the economic realities of their developing country, and to establish a more stringent arsenic standard would place an undue financial burden on both public and private water suppliers. Yet even with this elevated allowable limit, almost 20 percent of the groundwater in Bangladesh contains arsenic at concentrations that make it unfit for human consumption. Arsenic levels in excess of 2,700 ppb have been reported, and the government estimates that 20–60 million people are drinking water with arsenic levels greater than 50 ppb.

It is thought that the best treatment for chronic arsenic poisoning (arsenicosis) is a diet high in protein (preferably meat) and vitamins, to aid in the methylation (conversion of arsenic to a nonbioavailable form) of inorganic arsenic. The resulting arsenic metabolites then are excreted in the urine as long as clean, arsenic-free drinking water is consumed. The rural poor of Bangladesh are particularly prone to arsenicosis,

as their drinking water contains elevated levels of arsenic and their diets are low in protein because it is expensive and difficult to obtain and preserve. The United Nations now estimates that up to 20,000 people a year in Bangladesh could die of drinking arsenic-contaminated water, and this figure may be low because of the long latency period for some types of arsenic-related cancers. This rate exceeds death tolls related to the more widely publicized environmental disasters of Chernobyl and Bhopal.

### POSSIBLE SOLUTIONS TO THE PROBLEM

Both the Bangladeshi government and relief agencies are working to develop solutions to the arsenic crisis. One is to redrill tube wells to greater depths to tap arsenic-free groundwater, although this is an expensive and logistically difficult solution to implement. As well depths increase, pedal pumps cannot provide sufficient lift to carry water to the surface, and the new wells will need to be fitted with electric or diesel fuel-driven pumps. Another solution is to teach Bangladeshi women a filtration technique in which contaminated water is passed through a series of three containers or jars, each holding cloth, sand, charcoal, and iron filters. This process removes much of the arsenic from the water. A similar filtering solution that uses alumina ( $\text{Al}_2\text{O}_3$ ) to absorb the arsenic is available. Even easier to implement is a photo-oxidation technique whereby water is placed in a clear plastic or glass jar, mixed with lemon juice, and allowed to sit in the sun for a few hours. Arsenic is drawn from the water as iron oxide precipitate. Once these oxides are allowed to settle or are filtered out, the water is suitable for consumption. Each of these filtering or treatment processes, however, results in an arsenic-rich residue that must be carefully disposed of to prevent soil or surface water contamination.

The presence of naturally occurring arsenic in groundwater is not limited to Bangladesh. Similarly contaminated aquifers have been reported in Taiwan, Chile, Vietnam, and even Switzerland, and the success of Bangladesh in addressing its arsenic-impacted water will have global implications for these and other countries that want to provide safe, reliable drinking water to their populations.

**barium** Perhaps the most famous outbreak of barium poisoning occurred several times in the Szechuan province of China, where high levels of barium chloride in table salt periodically produced transient paralysis known as Pa-Ping disease. This potent toxin, however, has caused many other environmental and public health problems. Barium and barium compounds can be divided into two types, the safer types, which do not dissolve in water, such as barium metal, barium sulfate, and barium carbonate, and the more dangerous types, which are water soluble, such as barium chloride, barium peroxide, barium nitrate, barium hydroxide, barium sulfide, barium permanganate, barium cyanide, barium chlorate, and barium acetate. Barium and barium compounds have been found in 798 of the first 1,662 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List) where they have been tested, a very high percentage. They rank number 109 of 275 most dangerous pollutants on the latest CERCLA Priority List of Hazardous Substances.

### PROPERTIES, USES, AND PRODUCTION

The element (metal) barium was discovered in 1774 and first extracted in 1808. It is a naturally occurring inorganic alkaline earth metal that changes from silvery white to silvery yellow if exposed to air. Barium as metal does not occur in nature; rather, it occurs in compounds, primarily barite (barium sulfate) and far lesser amounts of witherite (barium carbonate). These two compounds are used to produce many of the other compounds. They and the other

barium compounds are commonly white powders or crystals. Barium sulfide is phosphorescent when exposed to light.

Imports of barite rose from 1.65 million tons (1.5 million metric tons) in 2002 to 3.0 million tons (2.7 million metric tons) in 2007 primarily from China (90 percent) and India (8 percent). Domestic production of barite increased from 462,000 tons (420,000 metric tons) in 2002 to 594,000 tons (540,000 metric tons) in 2007. Production was largely from three mines in Nevada and a significantly smaller mine in Georgia. Almost 95 percent of the barite in the United States is used to increase the density of well-drilling fluids for the petroleum industry. The rest has been used as a filler, extender, or weighting agent in paints, plastics, and rubber, and in some specific uses including brake and clutch pads for cars and trucks, automobile paint primer for metal protection and gloss, photographic paper, and additions to the cement jackets around pipelines under water. Barite is part of the mold-release compounds in the metal casting industry. Barite significantly blocks X-rays and gamma rays and is used in concrete for radiation shielding around X-ray units in hospitals, nuclear power plants, and nuclear research facilities. Ultrapure barite as liquid is used for contrast in medical X-rays. It is an ingredient in faceplate glass in the cathode-ray tubes of televisions and computer monitors.

Witherite is used in optical glassmaking (45 percent of use), in brick making (25 percent), in barium ferrites (7 percent), and as photographic paper coating (4 percent); 19 percent is employed in other applications such as case-hardened steel and as a rodenticide. Barium chloride is used in pigments, glass, dyes, leather, and chemical manufacture. Barium peroxide is used in bleach, dye, fireworks, chemical manufacture, welding, and tracer bullets. Barium nitrate is used in ceramic glaze, electronics, neon lights, fireworks, tracer bullets, and detonators. Barium cyanide is used in electroplating and metallurgical applications. Barium hydroxide is used in motor and lubricating oils, grease, plastics, papermaking, sealing compounds, pigments and dyes, polyurethane foam, vulcanization, and coating of limestone. Barium chlorate is used in matches, dyes, fireworks, and explosives.

### ENVIRONMENTAL RELEASE AND FATE

Barium and barium compounds occur naturally in igneous and sedimentary rocks and are released into the environment by weathering as nonpoint source pollutants. They are also released as point source pollutants from mine spoils, ore processing facilities, petroleum drilling operations, copper and steel

foundries, chemical manufacturing plants, landfills, and other disposal sites. The relative mobility and persistence of barium in the environment depend upon the compound. Barium metal, sulfate, and carbonate are highly persistent, but compounds such as barium chloride, barium nitrate, barium acetate, and barium hydroxide dissolve easily in water and do not persist. The liberated barium commonly then precipitates out as less toxic compounds, such as barium sulfate or carbonate, depending upon the chemistry of the water. Barium was found in virtually every surface water sample tested (99.4 percent) in a major domestic survey, primarily derived from natural sources. Some marine species can concentrate barium seven to 100 times ambient levels in water, and some marine plants can concentrate it 1,000 times. Barium is relatively immobile in most soils depending upon the chemistry. Dissolved organic compounds can have higher mobility and leach into the groundwater system. In some states, including Illinois, Kentucky, Pennsylvania, and New Mexico, there are communities where the levels of barium are 10 times higher than the EPA drinking water standards. Barium is released into the air through smokestack emissions from industry (metals and chemicals), incineration, and combustion of coal and oil and as windblown dust from natural sources. Most attaches itself to particulate (dust) and settles to the surface, directly as particles of barium or washed out by precipitation.

During the 1987–93 EPA Toxics Release Inventory, about 58 million pounds (26.4 million kg) were released by industry into the environment, about 99 percent of that to land. The states with the highest releases, in order, were Arizona, Utah, Virginia, New Mexico, Illinois, Tennessee, Alabama, Pennsylvania, Texas, and New Jersey, from copper and steel works, industrial organic and inorganic chemicals, car parts, and paper mills.

### HEALTH EFFECTS FROM EXPOSURE

The soluble barium salts and in some cases barium carbonate are highly toxic. Acute oral ingestion of barium salts can affect the central nervous system and cause vomiting, diarrhea, anxiety, decreased heart rate, increased blood pressure, cardiac irregularities, muscle weakness and tremors, numbness and paralysis, and ultimately death of cardiac and respiratory failure with increasing dosage. Fatal dosage for humans is about 0.8 gram (0.03 ounce) in most cases. Long-term chronic exposure by ingestion or inhalation of dust primarily affects the cardiovascular system. Inhalation exposure can produce a benign pneumoconiosis condition called

baritosis, in addition to symptoms common to ingestion exposure such as high blood pressure, decreased body weight, and reproductive damage including increased fetal mortality in laboratory animals.

### REGULATIONS ON HUMAN EXPOSURE

Barium is regulated by federal agencies because of its public health threat. The EPA established a drinking water limit of 2 ppm under the Safe Drinking Water Act. The Occupational Safety and Health Administration (OSHA) has set the permissible exposure limit (PEL) at 0.5 milligram of soluble barium per cubic meter of workplace air and 15 milligrams of barium sulfate dust per cubic meter for an eight-hour-workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) set their Immediately Dangerous to Life and Health (IDLH) designation at 50 milligrams of barium chloride per cubic meter of workplace air.

**beaches** Beaches are long, thin belts of sediments that mantle the continents at their shorelines. The sediments on beaches are predominantly sand, but in areas where there is a rocky coastline, in tectonically active areas, or in areas that have been glaciated in recent geologic history, beaches can have a variety of grain sizes. Sand on beaches is derived primarily from erosion of rocks exposed at the surface on the continental interior and carried to the shoreline by rivers and streams. There waves spread the sand along the coast. In far northern areas and in Antarctica, beach sediment is predominantly glacial in origin, although wave action on rocky shorelines is producing increasing amounts of water-eroded beach sediment in recent years. In areas north of New York City on the East Coast, much of the beach sediment was introduced during the last ice age. In modern times, with the damming of many rivers in populated areas, sediment cannot reach the mouth of the river and is sequestered in the bottoms of reservoirs, causing many beaches to become sand starved, spurring costly replenishment programs to be initiated to save them.

The long trip from the continental interior to the beach wears down the sediment and results in the alteration of unstable rock and mineral fragments into clay. The result is that primarily quartz sand and clay arrive at the river mouth. The clay is swept out to sea, and the quartz sand is transported onto the beach. In tropical areas with good reef development, sands may be composed primarily of calcite from pulverized coral and seashells. As waves and storms attack the reef, pieces of shell and coral break off and are mixed with the sand being pushed shoreward. Even quartz sand is coated with calcite in many areas, demonstrating the close interaction between biological (reef growth) and nonbiological beach forming processes. Where a rugged terrain reaches the coast, sands may be composed of any number of unstable mineral and rock fragments. In Hawaii, beaches are commonly black and composed of sand made of volcanic rock fragments. There was even a green beach composed of olivine (peridot), but it was covered by a recent lava flow. Such beaches are typically small and short-lived, as the unstable rock fragments composing them are readily altered to clay and other minerals.

### WAVES

The shape and dynamic processes on beaches are largely controlled by wave action. Waves are generated by the friction of winds blowing across the ocean surface. The area of ocean surface across which the winds act is the fetch. The stronger and more persistent the wind, the larger the waves.

**Block diagram showing how waves approach the beach. Water particles move in a retrograde circular path in open water. The deepest level in which water particles move is called the wave base. When the wave base hits the seafloor, it drags on it and the wave tips over and “breaks.”**

Ocean waves are surface waves that penetrate only the top layer of the water. In open water, they move as symmetric sinusoidal waves with all of the physical aspects including a crest at the top and trough at the bottom, with a measurable wavelength, amplitude, and period. These waves cause individual particles of water to move in orbital (circular) motions that are retrograde (backward) with respect to the forward motion of the wave. Orbital motions in the water occur in a vertical stacked configuration so that each orbital motion becomes smaller at increasing depth below the water surface. At a depth of one-half of the wavelength, the wave base forms a surface below which no water particle motion takes place.

As waves approach a beach, the wave base makes contact with the seafloor. The drag of the waves on the seafloor causes the waves to tilt, so the orbitals no longer align and are no longer round. The wave becomes asymmetric, leaning over toward the beach. As the water becomes shallower, the waves rise up and fall forward as they enter the breaker zone. Water flows forward quickly in the swash zone (the area of the beach along which waves break) and is driven up the beach face as the crest passes. As the trough passes, water retreats back down the shore face. This continuous passage of crests and troughs creates the back-and-forth motion of water at the

beach. The height of the waves that consequently reach up the beach face depends upon the amount of energy imparted to the water from such factors as winds, tides, seasons, and weather conditions.

Above the shore face is a flat area called the berm, and farther landward are the dunes. The size and shape of the shore profile depend on the weather and season. In winter, waves tend to be much larger and stronger. They remove sand and store it in sandbars offshore. The berm tends to be narrower during these times, and the shore face is much steeper. The gentle summer waves plow the sand back onto the beach, widening the berm and reducing the slope of the shore face.

The angle of approach of the wave crests to the shore determines the migration of sand along the beach. If the wave crests are parallel to the shore, there will be no lateral migration of sand. If the wave approaches the shore at an angle, water is pushed laterally along the shore in a *longshore current*. This current carries sand laterally along the beach in a process called littoral drift. The higher the angle between wave crests and the shoreline, the stronger the longshore current and littoral drift are. Beaches have been called rivers of sand because of their constant movement. If beaches were all straight and free of obstructions, there would be no other operative processes, but this is not the case.

**Block diagram showing waves approaching the beach at an oblique angle. The approach angle forces water laterally along the beach, forming the longshore current. The lateral currents force sediment along the beach in a sawtooth pattern caused by the breaking waves. The lateral sediment movement is called littoral drift.**

Where shorelines have embayments, or spits of land, longshore currents may become complex. When waves approach the shore, they slow as the result of friction with the seafloor. If part of the wave approaches the shore while the rest is still in deeper water, as in the case of a spit or embayment, part of the wave will slow, causing it to bend, or *refract*, as it continues to move. Such a geometry may cause longshore currents to move locally in opposite directions. Where they diverge, the sand may be eroded and removed. Where longshore currents converge, however, there is a buildup of water, which quickly escapes to deep water, forming a dangerous *rip current*. Rip currents can pull swimmers very quickly out to sea, thereby posing a threat of drowning to humans.

Certain types of shoreline features can disrupt the flow of the river of sand, resulting in sand-starved beaches in some areas and sand accumulations in others. Piers, groins, and jetties are structures that

extend directly away from the beach into deeper water that can obstruct the flow of sand. The sand will accumulate on one side of the obstruction, slowly diverting the flow of the longshore current. Eventually, enough sand will be deposited around the structure to allow longshore currents to flow around the obstruction and continue uninterrupted down the coastline. Sand will eventually return to the beach, but the area directly down flow of the obstruction will be sand starved and form an embayment. Breakwaters are obstructions placed just offshore to lessen the power of incoming waves. When the moving water that carries sediment encounters the breakwater in the protected area, it slows, loses energy, and drops its suspended sediment load. The area behind the breakwater fills with sediment, and the sand river simply goes around it, forming a bump in the coastline. It is human practices such as the installation and maintenance of groins, jetties, and breakwaters that cause an otherwise straight and stable beach and coastline to become scalloped and develop sand supply problems. The result may be the need for costly replenishment projects in which sand is moved from deeper water back to the beach or even transported from other areas, thus disrupting the ecosystem of both the supply and replenishment areas.

## BEACHES AND POLLUTION

Pollution of beaches can take many forms. In the United States, there are laws prohibiting the dumping of raw sewage into the ocean, but prior to 1972 and still in much of the rest of the world, this was not the case. Sewage effluence introduces both bacteria and nutrients to grow bacteria that can be harmful to both marine life and humans, causing sickness and disease, both directly to people and animals that enter the water and indirectly to people and animals that consume seafood from infected areas. This is a particular problem with filter feeders and especially shellfish, as the latter are sensitive to bacterial outbreaks. The most common such disease is hepatitis A, which is severe and potentially fatal, but there are many other diseases that can be caused by sewage effluences, as well.

Increased nutrients in coastal seawater from point sources such as sewers or nonpoint sources such as runoff from agricultural areas or even residential areas, coupled with higher temperatures, may also cause dangerous algal blooms. One of the more frequent dangerous algal blooms on the eastern seaboard in recent times is called red tide. In red tide, algae called dinoflagellates multiply in great numbers, turning ocean water a red-brown color. Depending upon the species of algae, mild to fairly

strong toxins, which can cause respiratory distress through airborne transport, even in people who do not enter the water, may be produced. In other cases, fairly strong neurotoxins that can damage or even kill marine mammals both directly and indirectly if they consume affected seafood can be produced.

**A diagram showing how longshore currents transport contaminated water along the coastline, thereby impacting an entire coastal area from a single pollutant spill or drain pipe: Liquid wastes are released offshore (A); continued injection of waste saturates the coastal littoral cell, and the saturated water moves progressively along the shore with the longshore current (B); the result is a strip of nearshore water, parallel to the coast, that is contaminated by liquid waste (C).**

These toxins are also dangerous and potentially fatal to humans if treatment is not administered quickly.

Recently beach pollution has also included washed up solid debris in the form of medical waste. Solid waste from a variety of sources washes onto beaches on a daily basis. Typically, it includes construction wood and general refuse and is largely just an eyesore. In more than one occurrence in 1988, however, beaches had to be closed in New Jersey because used hypodermic needles, sample containers, and gloves, among other medical waste, washed up onto the beaches. This type of waste was also found on Long Island, New York, beaches and several others. In most cases, the source of the waste was never determined, but the incidents underscored the generally poor disposal methods for even dangerous waste.

Oil, fuel, and chemical spills can cause long-term disruption of the operation of a beach. They are by far the most devastating form of beach pollution in terms of impact on the ecosystem and local economy. Oil is the most common and voluminous of the spill types and as such destroys the local ecosystem by overwhelming it. Typically, spills are from grounded tankers, storage and transfer facilities and directly from oil wells. Fuel and most refined chemicals are toxic to marine life, so even small amounts can be devastating. Minor amounts of fuel can be spilled from the tanks of ocean vessels, but more commonly spills result from accidents during transfer of fuel or from leaking storage facilities. Fortunately, fuel evaporates quickly, so the effects tend to be short-lived.

**Beaufort Dyke Irish Sea, Scotland (1969–present) Water Pollution** Francis Beaufort (1774–1857) was an Irish sailor who had an almost insatiable curiosity about the ocean, its currents, and winds. As

a merchant sailor, he nearly died of starvation at the age of 15 after being shipwrecked because of a faulty chart. Because of this experience, for the rest of his life he dedicated himself to gathering information about the coastlines, tides, and currents of the world's oceans. Many of the tide and shoreline charts he compiled are still in use today, 150 years after his death.

While in the British navy, Beaufort noticed with dismay that most wind observations were subjective. One officer's calm conditions might be another's moderate breeze. In 1805, Beaufort proposed a 0–12 scale based on how the sails of a “man-of-war,” a ship armed with cannon and propelled primarily by sails, were responding to the wind. Zero meant “just sufficient to give steerage”; 12 indicated a wind “that which no canvas could withstand.” By 1830, the Beaufort scale was the standard for ship's log entries in Royal Navy vessels, and, by the 1850s, it began to be adapted for general maritime use. It later would be modified to add categories 13–17 for hurricane conditions and become more quantitative as steam power gained widespread use and shipborne cup anemometers could accurately measure actual wind speed.

Although he did not have much formal education, Sir Francis Beaufort (knighted in 1848) was a strong supporter of numerous scientific and oceanographic expeditions. He served as a council member of the Royal Society, the Royal Observatory, and the Royal Geographic Society. Using these positions to promote worldwide studies of the ocean, he often lobbied to place scientists in key posts within both military and commercial expeditions. For example, one of his more interesting appointments was to recommend a relatively unknown biologist, Charles Darwin, as the naturalist for the HMS *Beagle*'s voyage to the Galapagos Islands.

Improperly discarded munitions pose both a safety and an environmental hazard. (Thomas J. Peterson/Alamy)

## POLLUTION OF THE DYKE

To honor Beaufort and his many scientific and nautical achievements, a 31-mile- (50-km-) long and 2.5-mile- (4 km-) wide submerged trench in the North Channel of the Irish Sea, between Northern Ireland and Scotland, was named Beaufort's Dyke. Dyke is a British term for “ditch” or “channel.” Beaufort's Dyke is just offshore the Scottish port of Cairnryan, where at the end of World War II, the German Atlantic U-boat fleet surrendered, eventually to be towed into the North Channel and sunk. Thousands of troops were based in and around Cairnryan, and the facility continued to play an important role in British military operations after the war. It was at this facility where obsolete and excess munitions were loaded onto barges and dumped into the 984-foot- (300-m-) deep waters of Beaufort's Dyke. The dyke's great depth and closeness to the coast, as well as the fact that it was not a significant fishery, were all important considerations in its selection as a munitions dumping ground.

Ocean dumping was a common and widely practiced way to dispose of surplus munitions. It seemed to be the most safe, efficient, and cost-effective method to get rid of these dangerous and unwanted materials permanently. After both world wars, and until 1976, approximately 2 million tons (1.8 million metric tons) of torpedoes, rockets, bombs, grenades, bullets, and explosives were jettisoned and dumped from barges and ships into Beaufort Dyke. Other materials disposed of in this trench include canisters of the weapon of mass destruction (WMD) nerve agents sarin and tabun, 120,000 tons (109,000 metric tons) of mustard and phosgene gas, cyanide, 330 tons (300 metric tons) of arsenic compounds, anthrax, as well as phosphorus bombs and radioactive waste including laboratory chemicals and luminous paint containing both cesium 137 and radium 226 that were thrown overboard in concrete-filled 40-gallon (182-L) steel drums. Most of the explosives are present at depths greater than 328 feet (100 m), but some of the material was “short-dumped”: The ships under contract to take the munitions out to the trench, whether because of poor weather, faulty navigation, or laziness, never made it and off-loaded their deadly cargo into the shallower seabed, closer to shore.

## THE POLLUTION WASHES BACK

The Irish Sea is an important commercial waterway that links Scotland and England to Ireland. The vast majority of goods and materials between these two important commercial centers move by ship. In addition, the Irish Sea is crisscrossed with pipelines and

telephone, electrical, and other types of cables that provide power, gas, and other services essential to both quality of life and British national defense.

Concerns about the long-term stability and safety of munitions dumped into Beaufort Dyke began to surface in 1966, when British naval authorities started to receive reports of underwater explosions in the vicinity of the disposal trench. Since then, a study of seismograph records by the British Geological Survey documented almost 50 explosions and concluded that it was very likely that many more undetected detonations had taken place.

One serious event took place in 1969 when the crew of the trawler *Aquilon*, who were bottom fishing outside the well-charted 12-mile (19.2-km) exclusion zone surrounding Beaufort Dyke, hauled their nets up and found in them canisters of Eperite, a type of mustard gas or blister agent. This World War I chemical weapon is absorbed through the skin and by inhalation and attacks the body's mucous membranes and respiratory system. It forms large painful blisters and leads to blindness, permanent lung damage, and death. Two of the crew were so severely exposed that their hair and skin began to peel off and their urine burned the skin on their legs and thighs.

In 1995, British Gas, a multinational supplier of natural gas and other types of energy, received permission to construct the Scottish–Northern Ireland Pipeline, a 24-inch- (61-cm-) diameter submerged conduit across the Irish Sea between the Scottish and Irish coasts. Submarine cables and pipelines must be encased in several layers of protective material and surrounded by a tough, flexible metal membrane, especially in an area of high ship traffic or heavy fishing such as the North Channel of the Irish Sea. A barge loaded with spools of cable or pipeline is stationed at the landward starting point and the seaward end of the cable is attached to a marine plow. This plow is towed behind a ship and digs a narrow trench into the seabed at depths of up to eight feet (2.5 m), simultaneously feeding the pipe into the trench. The soft marine sediments quickly resettle into and fill or collapse the trench, effectively protecting the cable from ships' anchors and fishing tackle. Similar protective techniques also can be used such as seafloor jetting or the placement of rocks or concrete mattresses. These and other cable protection methods are most commonly used closer to shorelines and in coastal waters, whereas open or unprotected cable laying is done in deeper ocean water.

British Gas installed its pipeline and meticulously followed all the environmental and routing requirements specified in its permits. One of these restric-

tions was to avoid the Beaufort Dyke and its large cache of discarded and increasingly unstable munitions. Shortly after the pipeline was installed, an estimated 4,500 incendiary devices, mostly phosphorus flares, began washing up on the Irish and Scottish coastlines. Press reports stated that it was not uncommon to see the beaches lit at night by the sparking and burning flares. In two separate incidents, a child and an adult were seriously injured when, out of curiosity, they picked up the hissing and popping metal tubes. Later investigations by the Royal Navy concluded that the pipeline had disturbed a previously uncharted pile of military ordnance that had been "short-dumped" near the Beaufort Dyke. Demolition teams were kept very busy that winter clearing the beaches of these dangerous flares.

Concerned that the presence of the munitions might have a deleterious effect on marine life, the Scottish Office of Agriculture, Environment and Fisheries Department commissioned a survey of the Beaufort Dyke area by its Marine Laboratory. Carefully collecting samples of seabed sediment, fish, and shellfish from within the Beaufort Dyke, the Marine Laboratory concluded that the near-surface seabed sand and silt did not contain detectable concentrations of chemical agents or other munitions. Neither did samples of fish and shellfish meat collected from within the Beaufort Dyke area. The munitions in this ocean disposal trench, therefore, pose more of a hazard to fishermen and beachcombers than to the coastal ecosystem, but careful monitoring of the Beaufort Dyke will be required for many years.

### **Bell Lumber and Pole Company New Brighton, Minnesota (1984–2001) Water and Soil Pollution**

Ever since prehistoric times, wood has played a key role in the survival and development of the human species. Even today, much of the world's commerce revolves around wood and wood products. Wood as a building material, tool, or container has limitations. If used outdoors or in contact with soil, it is susceptible to rot (by water, bacteria, and fungi) and damage by insects. Its appearance also can change, depending upon the environment to which it is exposed. To overcome these limitations, a wide variety of techniques have been developed to maintain the longevity and usefulness of wood and wood products. One method is coating it with pitch, a very viscous, or semisolid, material derived from the sap or resin of plants. Pitch also can be prepared from petroleum, called tar, or bitumen. The ancient Greeks soaked wood used in bridge construction in olive oil to waterproof it, and Romans tarred the hulls of their ships to keep them watertight.

These methods only treated the outside surfaces of the wood, similarly to paints, stains, and sealants, and had to be regularly reapplied or their effectiveness was limited. Today, four primary methods of commercial wood treatment dominate the market: water-based preservatives including chromated copper arsenate (CCA), sodium phenylphenoxide, benzalconium chloride, and guazatin; solvent-based preservatives including pentachlorophenol (PCP), propiconazol, tebuconazol, lindane, permethrin, triazoles, and tributyltin; oil-based preservatives including creosote; and preservatives intended to slow combustion and ammonium salts, borates, phosphates, bromides, and antimony oxides. In all four methods, the preservation process involves impregnating or saturating the wood with chemicals to protect it from biological decay (rot or insect damage) or change in appearance and/or retard combustion.

Treated wood used to be dipped in chemicals that would spill and wash off, but now it is mainly pressure treated. In pressure treatment, wood is placed inside a cylinder that is flooded with preservative. The cylinder then is sealed and all the air removed, creating a vacuum that forces or drives the preservative into the wood. Pressures in the range of 800–1,400 kilopascals (kPa) typically are needed to ensure effective impregnation of the wood. Water-based chromated copper arsenate (CCA) preservative is the most common in the United States and accounts for about 90 percent of the market.

Some studies indicate that CCA can be flushed out of the wood and migrate to nearby soil. Small amounts of CCA are sometimes present on the sur-

face of treated wood. These residues can contaminate food or be transferred to human skin (particularly children's) and may result in unacceptable levels of arsenic exposure. The U.S. Consumer Product Safety Commission recommends that playground equipment be painted or sealed with an oil-based sealer every two years to reduce the potential for exposure to CCA-related compounds. Research on the use of CCA-treated lumber in vegetable gardens has not shown that these chemicals affect the quality or safety of domestic produce.

Of the organic solvent-based preservatives, the most common is pentachlorophenol. A crystalline aromatic compound, PCP is a probable human carcinogenic and toxic organochloride fungicide. It is often contaminated with other toxic organic chemicals such as chlorinated phenols, dioxins, and dibenzofurans, and PCP is a common ingredient in pesticides. Still widely used in industrial settings, PCP helps preserve utility poles, railroad ties, piers, and other lumber destined for commercial applications. The sale and use of PCP were restricted by the U.S. Environmental Protection Agency (EPA) in 1987, and it can only be purchased by specially licensed businesses.

The most common oil-based preservative is creosote, a heavy black-brown liquid produced by condensing vapors from heated carbon-rich sources, such as coal, coal tars, or wood, most commonly beech. As a wood preservative, it is only used in commercial applications and cannot be purchased or applied at a retail or homeowner level. Its registered uses include serving as a fungicide, insecticide, miticide, and sporicide to protect outdoor wood and wood products, primarily utility poles and railroad ties. Approximately 70 percent of the railroad ties in the United States are made with creosote-treated wood, along with 20 percent of all utility poles. It is the most widely used wood preservative in the United States.

### **TREATMENT OPERATIONS**

The Bell Lumber and Pole (BL&P) Company and its next-door neighbor, the MacGillis and Gibbs (M&G) Company, were wood treatment businesses that used chemicals such as creosote and PCP to preserve railroad ties, telephone poles, and landscaping timbers. About 12 miles (19 km) northwest of downtown Saint Paul, both companies began operations in 1918 as storage yards for telephone poles. By the 1920s, they were operating on a combined 24-acre (9.7-ha) parcel, using creosote to treat telephone poles and railroad ties. Creosote usage at both sites ceased around 1960. For the purposes of this

description, both sites will be referred to jointly as M&G.

Initial wood preservation operations at the M&G site consisted of inserting the butt end of a telephone pole (the section of pole that would be in contact with the ground) into a vat or open-topped tank of hot creosote. The pole then would be removed and allowed to air dry. By the late 1940s, M&G began using a mixture of PCP dissolved in a heavy fuel oil and used tanks about 10 times the volume of the original butt tanks so that the entire pole could be submerged in the treatment chemical. In the 1960s, the process changed with the addition of less dense oil as a carrier fluid for the chemicals. This new oil was lighter than water and tended to trap moisture given off by the wood during treatment. The water recovered in this process, whose volume was quite large, along with spent treatment chemicals, was routed to a pond in a low-lying area in the west central portion of the site. By 1970, M&G had ended the use of PCP and switched to CCA.

Land use around M&G was a mix of residential, commercial, and industrial, with the closest homes within a few hundred yards of the site. Several of these homes used groundwater as their source of drinking water. Numerous lakes and streams are within a few miles of the site, and some are used for recreational purposes. Wetlands are present northeast of the site, and these serve as ecological habitats for migratory and native animal and plant species.

By the late 1970s and early 1980s, wood treatment facilities nationwide were coming under scrutiny of the EPA as having the potential to create significant environmental problems. Sloppy handling and waste management procedures, including letting excess chemicals drip from treated lumber directly onto bare soil and letting spillage from treatment tanks run off into local waterways, were causing soil, surface water, and groundwater contamination at sites from New England through the Pacific Northwest.

### INVESTIGATION AND CONTAMINATION

In 1979, M&G reported a spill of 4,000–5,000 gallons (15,142–18,927 L) of CCA solution. This triggered a series of investigations by both EPA and the Minnesota Pollution Control Agency (MPCA) that focused on M&G's waste management practices. MPCA and EPA inspectors began to visit the site regularly to investigate how its spent chemicals and process wastewater were being managed. Many violations were recognized. Some 200 drums containing depleted and used PCP, many in poor condition, were scattered about the site. Also present were unused and abandoned process tanks, some

containing significant quantities of creosote residues. Perhaps the most serious problem was a disposal pit that contained approximately 30,000 cubic yards (22,937 m<sup>3</sup>) of contaminated debris, including treated poles and posts, wood shavings and chips, asphalt, concrete, and processed PCP waste. This pit had been covered with a few feet of soil in an attempt to isolate it from the environment and lessen its visual impact. According to accounts provided by longtime M&G employees, similar fill activities had taken place in low-lying areas along the west central portion of the site. Another approximately 19,000 cubic yards (14,527 m<sup>3</sup>) of metal-contaminated soil was identified in and around the CCA process area.

Alarmed that nearby residents might be exposed to PCP and other treatment chemicals, the EPA and MPCA began a groundwater investigation, and the wells of six nearby homes were sampled. A plume of LNAPL—light nonaqueous phase liquid (oil)—was found to be floating on top of the groundwater underlying the site, and five of the six private wells sampled contained detectable levels of PCP. On the basis of these factors, Bell Lumber & Pole and MacGillis & Gibbs were added to the EPA National Priority List as a Superfund site in 1984.

### REMEDIAL ACTIONS

The EPA and MPCA directed a series of remedial activities designed to stabilize the site and prevent further environmental degradation. The drums were overpacked and removed for disposal at an approved hazardous waste management facility. Obsolete and out-of-service process vessels and piping were cleaned and dismantled, and underlying contaminated soil was excavated and shipped off-site. A special recovery, or “pump-out,” well was installed to remove LNAPL present in the groundwater and a monitoring program begun to continue to check nearby homeowner wells, many of which were now only being used for purposes other than human consumption or contact (e.g., lawn watering or car washing).

Eventually, the EPA and MPCA excavated the disposal pit to a depth of 10 feet (3.1 m) and removed the material to an approved waste management site. This pit was backfilled with less contaminated soil removed from around the site and then covered with a specially designed cap. In this way, the majority of both properties would be remediated with the high-volume, low-risk material effectively contained. The cap will need to be monitored for many years to make sure its integrity is maintained.

Although Bell Lumber and Pole (BL&P) and MacGillis and Gibbs (M&G) were listed as one site, the

reactions by each company to their cleanup obligations were very different. BL&P, a longtime family-owned business, almost immediately entered into a cooperative agreement with the EPA and MPCA to investigate their portion of the site and to participate in funding the \$10-million cleanup. BL&P continues to operate on its portion of this property with a now much more environmentally aware and conscientious attitude. M&G filed for bankruptcy shortly after MPCA and EPA began their investigations and, although it operated for about another 10 years, closed its doors in 1997.

The EPA conducted a five-year review of remedial program effectiveness in 2006 and concluded that cleanup activities completed at the site were protective of human health and the environment, and that potential exposure pathways for waste remaining on site were being controlled. Recently, the city of New Brighton purchased the former M&G property and has redeveloped it for use by a plastics manufacturing company. In addition, two office buildings and a retail store have been built. This formerly contaminated property has now been restored to productive use.

**benzene** Benzene is an organic compound from natural and industrial sources and is extensively

used in industry and widely distributed as point source and nonpoint source pollution. It ranks in the top 20 in production of all industrial chemicals in the United States. It is a versatile chemical used for numerous and important industrial applications. It is used as the base for plastics and synthetic fibers such as Styrofoam and other plastics, various resins, cyclohexane for nylon, and other synthetics. It is also used to manufacture certain rubber products, lubricants, dyes, detergents, drugs, and pesticides, and it is present in the BTEX (benzene, toluene, ethylbenzene, xylene) component of oil and gasoline. Although critically important as a commercial manufacturing product, benzene also is regarded as a serious environmental contaminant, ranking sixth on the 2007 CERCLA priority list of 275 most hazardous environmental pollutants. Of the first 1,662 U.S. Environmental Protection Agency (EPA) Superfund sites (National Priorities List), benzene was present in 1,001 of those where it was tested. There are few, if any, pollutants that are more widespread than benzene.

#### PROPERTIES, PRODUCTION, AND USE

Benzene was first discovered in the late 19th century as a by-product of coal tar, but later it was found as a derivative of petroleum, as well. In addition to occurring as a natural component of oil and coal, it is also emitted as part of volcanic eruptions and is a by-product of burning, especially from forest fires and cigarette smoke. Benzene can exist as a liquid, vapor, or gas. It is a clear, colorless liquid that evaporates readily and is highly flammable. It has a strong, pungent, sweetish odor and slightly dissolves in water. It can be smelled at 1.5–4.7 parts per million (ppm) in air and about 2 ppm in water. People can taste benzene in water at 0.5–4.5 ppm. More than 12 billion pounds (5.5 billion kg) of benzene was produced in the United States in 1993, a significant increase over the 9.9 billion pounds (4.5 billion kg) produced in 1984, and demand is increasing.

#### ENVIRONMENTAL RELEASE AND FATE

More than 2 million pounds (909,090 kg) of anthropogenic benzene was released into the environment between 1987 and 1993 according to the EPA Toxics Release Inventory. In 2006, according to the inventory, 5,959,781 pounds (2,708,891 kg) of benzene was disposed of or released to the environment. These accidental releases primarily occurred at oil refineries, with much smaller releases in the metals and chemical industries. The most affected state is Texas, which has six times the volume of accidental

release of Alabama, the second most affected state, followed by Louisiana, Colorado, New Mexico, and Illinois. Benzene can also have numerous nonpoint sources that provide the primary exposure for most Americans including automobile exhaust, power generation from fossil fuels, evaporation from gas stations, and gasoline leakage from underground storage tanks (USTs) at gas stations. Cigarette smoke can also greatly increase benzene concentrations in indoor air. Cigarette smokers, on average, inhale about 1.8 milligrams of benzene per day in smoke, which is about 10 times the total exposure for non-smokers. Inhalation of benzene is by far the most prevalent form of exposure, but ingestion of food, water including bottled water, liquor, and other beverages may also provide significant doses depending upon the source. It is estimated that some 238,000 Americans work in industries where they may be exposed to greatly elevated levels of benzene relative to the general population. Certainly, many of these people work in the industries previously described, but even gas station attendants and firefighters have potentially elevated exposure.

In the natural environment, the persistence of benzenes depends upon a number of conditions. In the atmosphere, it mainly exists in the vapor phase and degrades relatively quickly. In polluted air, it can react rapidly to form other compounds with a removal half-life of four to six hours, whereas in clean air the half-life is more than 13 days. Precipitation can readily remove benzene from air and deposit it into soil and surface water. Benzene in surface water is subject to quick evaporation depending upon wind speed and temperature. It can undergo biodegradation in aerobic surface waters with a calculated half-life of 16 days. In marine environments, degradation was found to have a two-day half-life in the summer and a two-week half-life in the spring, but no degradation was found in the winter. In winter, photodegradation can still remove benzene at the rate of 17 days for the half-life. In soil, benzene evaporates quickly near the surface, but it is highly mobile and tends not to bind to soil. That which is not volatilized typically undergoes significant biodegradation under aerobic conditions but little to no degradation under anaerobic conditions. Rapid infiltration and underground migration of benzene quickly transmit it into the groundwater system, where it poses the greatest environmental threat.

### HEALTH EFFECTS FROM EXPOSURE

Benzene causes significant adverse health effects. Inhalation of benzene typically causes drowsiness, dizziness, headaches, tremors, rapid heartbeat,

confusion, and finally unconsciousness. Even brief exposures to very high levels can be fatal through depression of the central nervous system. Benzene contact with skin results in rashes and lesions, and contact with eyes causes irritation and damage to the cornea. Ingestion of high levels of benzene causes vomiting and irritation of the stomach, followed by the same symptoms as inhalation including coma and death. It operates directly through the liver but also targets the kidneys and brain among other organs. Chronic long-term exposure to low or moderate levels of benzene results in numerous adverse effects including disruption of normal blood production, especially in the bone marrow. Symptoms include the onset of mild to serious anemia, as well as excessive bleeding potentially leading to death. Damage to the central nervous system is also probable including peripheral nerve damage and atypical sleep activity. Chronic exposure to benzene can also damage the immune system leading to increased infections. It is also harmful to reproductive organs and may damage fetuses. Studies show that with prolonged exposure, women had irregular menstrual periods and showed a decrease in the size of their ovaries. Animal studies indicate that exposure of pregnant females to benzene can have harmful effects on developing fetuses including low birth weight, slow bone development, and damage to bone marrow. Chronic exposure to benzene has also been shown to increase significantly the risk of cancer in the form of acute myeloid or erythroblastic leukemias and chronic myeloid and lymphoid leukemias, cancers of blood-forming and lymphatic organs. Animal studies have also found that benzene exposure can cause a variety of cancers in organs including the lungs, skin, mammary glands, ovaries, oral cavity, and the Zymbal gland. The EPA, Department of Health and Human Services, and the International Agency for Cancer Research have classified benzene as a carcinogen.

### REGULATIONS ON HUMAN EXPOSURE

Benzene exposure is regulated by all of the pertinent federal agencies because of its widespread distribution and adverse health effects. With a goal of 0 ppm, the EPA limits the maximal amount of benzene in drinking water at five parts per billion (ppb) under the Safe Drinking Water Act. The surface water goal is also 0 ppm. A maximal level of 200 ppb is recommended for short-term (10 days or less) exposure for children. They further require that the National Response Center must be notified in the event of a benzene spill of more than 10 pounds (4.5 kg). The Occupational Safety and

Health Administration (OSHA) has determined that the maximal allowable exposure to benzene in air is 1 ppm for an eight-hour workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) recommends that workers be fitted with respiration air filters if they are exposed to concentrations exceeding 0.1 ppm for an eight-hour workday. They set their immediately dangerous to life and health (IDLH) designation at 500 ppm in workplace air.

**benzidine** When the federal government became involved in regulation of substances of environmental concern, there were chemicals that went from very common production and use to virtual abandonment over just a few years. Benzidine is one of those chemicals. It is classified as a group A human carcinogen by the U.S. Environmental Protection Agency (EPA), and production was effectively banned in the United States by the Occupational Safety and Health Administration (OSHA) regulations in 1973. By 1976, all large-scale domestic production had ceased, and since then only small amounts of benzidine have

been available for diagnostic testing and research laboratory applications. Benzidine is a synthetic compound that is a nitrogen compound, aromatic amine, and also known as 4,4-bianiline, 4,4-biphenyldiamine, 1,1-biphenyl-4,4-diamine, 4,4-diaminobiphenyl, p-diaminophenyl, among other names, and commercially as Fast Corinth Base B with numerous congeners including o-toluidine and o-dianisidine. It is most commonly present as salts such as benzidine hydrochloride and benzidine sulfate, appearing as a grayish yellow, white, or reddish gray crystalline powder and paste. It is present in only 28 of the first 1,585 EPA-designated Superfund sites (National Priorities List) where it has been tested; yet, it is ranked as number 26 of 275 most dangerous pollutants on the 2007 CERCLA Priority List of Hazardous Substances because of its toxicity.

### PRODUCTION AND USE

Benzidine was invented in 1845 and first produced in a dye (Congo red) in 1884. It was used extensively for more than 100 years and since 1914 primarily in the production of azo dyes, sulfur dyes, fast color salts, naphthols, and various other dyeing compounds. The dyes were primarily used for textiles (25 percent), leather (15 percent), and paper (40 percent). It was also a rubber compounding agent, used in the manufacture of plastic film, and in diagnostic laboratories for the detection of blood, hydrogen cyanide, and sulfate; for the detection of hydrogen peroxide in milk; as a reagent for sugars and a stain for microscopy; and for quantitative determination of nicotine. There are more than 300 colors from benzidine-derived dyes, 18 of which were available in the United States, and of those, 11 were manufactured domestically. The primary dyes were direct black 4,8; direct blue 2,6; direct brown 1A, 2, 6, 31, 59, 74, 95, 154; direct green 1, 6, 8; direct orange 8; direct red 1, 28, 37; direct violet 1, 22; and acid red 85. The peak production for benzidine dyes in the United States was in 1948, when 31 million pounds (14 million kg) was produced. In 1972, the last year before the ban, more than 10 million pounds (9,900 metric tons) of benzidine compounds was produced domestically. In comparison, the domestic production in 1977 and in 1983 was 500 pounds (227.3 kg) each year, though imports totaled 8,900 pounds (4,000 kg) in 1980. Benzidine dye production was still 6.4 million pounds (2.9 million kg) in 1976 but declined to 1.7 million pounds (780,000 kg) by 1978 and continued to decline thereafter. Imports of benzidine dyes were 600,000 pounds (272,000 kg) in 1976, 1.6 million pounds (730,000 kg) in 1978, and 469,000 pounds (213,000 kg) in 1979. In 2003,

there were still nine suppliers in the United States but no manufacturers of benzidine.

### ENVIRONMENTAL RELEASE AND FATE

In the past, benzidine was released to the environment primarily as a point source pollutant from manufacturing facilities as liquids into surface waters or as dust and fumes. Leaks and spills from storage and transport operations also contributed significantly, as did legal and illegal dumping. Today, it enters the environment primarily as leaks from old waste sites. In surface water, benzidine typically sinks and adheres to bottom sludge and sediments, where it tends to remain strongly fixed. Benzidine salts and dyes can dissolve more easily into surface water. In soil, it attaches strongly to clays and organic particles, and, as a result, very little leaches into the groundwater. Degradation in soil is primarily through the activity of microorganisms. In the atmosphere, benzidine exists as very small airborne particles or as vapor that also tends to attach to particles. It can be destroyed by reaction with photochemically produced hydroxyl ions, but it most commonly returns to Earth as fallout or as precipitation washout. Ever since the ban, environmental releases of benzidine have been relatively minor: Releases reported in recent years are 16 pounds (7 kg) in 1993, 250 pounds (113 kg) in 1994, two pounds (1 kg) in 1999, and 532 pounds (241 kg) in 2001. The last reported release of benzidine dyes was in 1989, when 750 pounds (339 kg) of direct black was released.

### HEALTH EFFECTS FROM EXPOSURE

There are numerous adverse health effects from exposure to benzidine, the most dire of which is cancer. It is very toxic to humans by acute exposure through ingestion, with health effects including cyanosis, headache, mental confusion, nausea, and vertigo. Skin exposure produces rashes and irritation. Long-term chronic exposure to benzidine appears to cause bladder injury in humans. Laboratory animals suffered numerous adverse health effects from exposure including damage to the liver, kidneys, circulatory system, central nervous system, and brain. Numerous studies have shown that exposure to benzidine causes an increased risk of bladder cancer in humans. Since it has been banned, the rate of bladder cancer has steadily decreased. Benzidine and benzidine dyes have also been implicated in cancers of the liver, kidney, larynx, esophagus, bile duct, gallbladder, stomach, and pancreas, but the connections are not definitive. Studies on laboratory

animals have documented numerous types of cancer from ingestion, inhalation, and injection exposure in mice, rats, hamsters, and dogs. These include cancer of the liver, mammary glands, colon, bladder, and Zymbal gland and injection site tumors.

### REGULATIONS ON HUMAN EXPOSURE

In addition to the ban, human exposure to benzidine is strongly regulated by federal agencies. The EPA limits the amount of benzidine in drinking water to less than one part per trillion (ppt) under the Safe Drinking Water Act, which is essentially 0 because one ppt is well below the detection limits of most analytical equipment. They further require that less than 0.1 part per million (ppm) of benzidine be present in waste taken to disposal sites and that the release of one pound (0.45 kg) or more to the environment must be reported to the National Response Center. The U.S. Food and Drug Administration limits food coloring to less than one part per billion (ppb) of benzidine. OSHA and the National Institute of Occupational Safety and Health (NIOSH) treat benzidine as a carcinogen. NIOSH estimated that 79,200 workers were exposed to benzidine dyes in their 1972–74 National Occupational Hazard Survey, and 10 years later, the 1981–83 National Occupational Exposure Survey estimated that 33,900 workers were exposed. The 1981–83 survey also estimated that 15,554 workers were exposed to benzidine.

**beryllium** Beryllium is a naturally occurring group II metallic element and the lightest of the heavy metals. This inorganic pollutant enters the natural environment both through natural processes such as the weathering of rocks and soils and volcanic emissions as well as through industrial production and waste disposal. Beryllium is derived from two economic minerals, bertrandite and beryl, the latter of which also forms the gemstones aquamarine and emerald with impurities of iron and chromium, respectively. Beryllium is used to produce a variety of industrial compounds including beryllium metal, beryllium-copper alloy, beryllium-aluminum alloy, beryllium oxide, beryllium hydroxide, beryllium chloride, beryllium phosphate (meta- and ortho-), beryllium sulfate (and sulfate tetrahydride), beryllium carbonate, beryllium silicate, and zinc beryllium silicate. It is a strategic metal with vital applications in the defense and aerospace industries. Beryllium is listed as a known human carcinogen and is present in 535 of the first 1,613 U.S. Environmental Protection Agency (EPA)-designated Superfund sites (National Priorities List) in which it was tested. It is ranked number 42 of the 275 most dangerous substances to the environment on the 2007 CERCLA Priority List of Hazardous Substances.

### PROPERTIES, USES, AND PRODUCTION

Pure beryllium is silver gray to grayish white and metallic. It was discovered in 1798 but not produced commercially until the 1930s and not until the 1940s in the United States. Beryllium oxide was not produced domestically until 1958. The United States is the world's largest producer of beryllium, primarily from the Spor Mountain area of Utah (18,000-ton [16,363-metric ton] reserve) and the Seward Peninsula of Alaska. Traditionally, the other main producers in order are Russia, China, and Kazakhstan, though Mozambique has recently increased production and Brazil has excellent beryl

deposits as well. Production in the United States was 253 tons (230 metric tons) in 1998 and 110 tons (100 metric tons) in 2002 with imports of 45.5 tons (50 metric tons) and 132 tons (120 metric tons), respectively. In 2005 and 2006, production was 121 tons (110 metric tons) and 110 tons (100 metric tons), respectively, with imports of 84.5 tons (93 metric tons) and 63.6 tons (70 metric tons). Pure beryllium is used to produce disk brakes for aircraft, windows for X-ray transmission, aerospace instruments and optics, parts for spacecraft and aircraft, missile components, nuclear weapons, nuclear reactor parts, fuel containers, rocket propellant, navigational systems, high-speed computers, audio components, heat shields, mirrors, and precision instruments. Beryllium alloys, primarily with copper and aluminum, are used in electrical connections and relays, precision instruments, parts for aircraft engines, submarine cable housings and pivots, automotive electronics, telecommunications, computers, home appliances, dental devices, golf clubs, bicycle frames, and many other applications. Beryllium oxide is used for ceramics, electrical insulators, parts of microwave ovens, armor for military vehicles, rocket nozzles, nuclear reactor fuels, components of lasers, automotive ignition systems, and thermocouple tubing; as a catalyst for organic reactions and in high-temperature reaction systems; and, in the past, in fluorescent lamp phosphors among other applications. Beryllium chloride is used as an acid catalyst in organic reactions and in production of beryllium metal. Beryllium fluoride is used in the production of nuclear reactors and glass. Beryllium sulfate is used in ceramics, and beryllium sulfate tetrahydride is used in the processing of beryllium ores. Other beryllium compounds have limited applications.

### ENVIRONMENTAL RELEASE AND FATE

Beryllium is released to the environment, primarily to the atmosphere from factories, incineration, and coal burning; and primarily to water and soils by the natural weathering of rocks. The estimated natural release of beryllium into the atmosphere is 5.5 tons (5 metric tons) per year from windblown dust and 0.22 ton (0.2 metric ton) per year from volcanic particles, whereas human sources include industry at 0.66 ton (0.6 metric ton) per year, metal mining at 0.22 ton (0.2 metric ton) per year, electrical utilities at 3.85 tons (3.5 metric tons) per year, and waste recovery at 15 pounds (6.8 kg) per year. It primarily exists as fine dust particles in air that may remain suspended for up to 10 days before settling to the ground or being washed to the ground

by precipitation. Anthropogenic beryllium in soil is mostly as a nonpoint source pollutant from atmospheric settling and washout by precipitation but also as the result of industrial dumping, mine waste, and incinerator and coal ash disposal as a point source pollutant. Most beryllium does not dissolve in water and remains fixed in the soil, where it may react to form other compounds, but it is unlikely to leach into the groundwater. Wastewater from mining and industrial applications can pollute surface waters, as can air pollution fallout and washout, but beryllium tends to settle quickly to the sediment in most freshwater settings. In the ocean, it can remain suspended for hundreds of years. During the Toxics Release Inventory of 1987–93, more than 340,000 pounds (155,000 kg) was released to land and water by industry. The states with the highest release were Pennsylvania and Ohio with smaller discharges in Michigan, Texas, and Minnesota, primarily through metal smelting and refining operations and petroleum refining.

### HEALTH EFFECTS FROM EXPOSURE

There are numerous adverse health effects caused by beryllium exposure. Acute exposure to it is primarily through inhalation and can result in acute berylliosis, which is characterized by rhinitis, pharyngitis, and tracheobronchitis and may progress to moderate to severe pulmonary symptoms depending upon dosage. Long-term chronic exposure typically leads to chronic berylliosis, which is a systemic disease that is more likely to be fatal than acute berylliosis. It primarily affects the lungs with the development of granulomas that can spread to the skin, bones, liver, kidneys, spleen, lymph nodes, myocardium, muscles, and salivary glands. The EPA first classified beryllium as a group B2 probable human carcinogen but upgraded it to a known human carcinogen in 2002. It has been shown to increase the incidence of lung cancer greatly in humans and possibly breast, bone, and uterine cancer as well. In laboratory rats, mice, and monkeys, beryllium also caused lung cancer, and it caused bone cancer in rabbits.

### REGULATIONS ON HUMAN EXPOSURE

As a result of severe adverse health effects and widespread distribution, federal agencies regulate human exposure to beryllium. The EPA regulates beryllium under the Safe Drinking Water Act to a maximum of four parts per billion (ppb). They further require the reporting to the National Response Center of any spill of beryllium of 10 pounds (4.5 kg) or more and one pound (0.45 kg) or more of beryllium chlo-

ride, beryllium fluoride, and beryllium nitrate. The Occupational Safety and Health Administration (OSHA) set the permissible exposure limit (PEL) at 2 micrograms of beryllium per cubic meter of workplace air for an eight-hour-workday, 40-hour workweek. They have further set an acceptable peak exposure level at 0.025 mg per cubic meter of air for a 30-minute exposure. The National Institute of Occupational Safety and Health (NIOSH) set a recommended exposure limit (REL) of 5 micrograms of beryllium per cubic meter of air on an eight-hour-workday, 40-hour-workweek basis with a designation of immediately dangerous to life and health (IDLH) limit of 4 mcg per cubic meter of air.

**Bhopal, air pollution disaster** *Bhopal, India December 3, 1984 Air Pollution* The release of methyl isocyanate (MIC) on December 3, 1984, from an agricultural chemicals plant in Bhopal, India, is arguably the world's worst industrial accident. The events leading up to the release have

been reasonably well documented, but its underlying causes are complex and its consequences far-reaching. From an environmental perspective, the deadly cloud of MIC that quietly floated over the city during an early winter temperature inversion did not result in lasting ecosystem damage. The vapors dissipated within a few hours, and no traces of residual MIC from the release could be found in soil, in groundwater, or on plants or vegetables. From a political and economic standpoint, however, Bhopal became a rallying cry for environmentalists around the world and played a major role in redefining governmental oversight and corporate environmental obligations, especially in developing countries.

### BACKGROUND ON THE PLANT

Very stringent precautions must be taken in the manufacture, transport, and processing of MIC ( $C_2H_3NO$ ). Used as one of the main ingredients in carbamate pesticides, it is a highly volatile, clear, colorless, pungent liquid. It reacts violently with water, quickly heating and boiling to produce isocyanic gas. MIC is highly flammable and has a low flash point. At temperatures below 102.4°F (39.1°C), it rapidly evaporates and, because it is heavier than air, tends to follow local topography and move downhill if released.

Exposure to MIC causes multiple adverse health effects. If inhaled at concentrations as low as 0.4 part per million (ppm), MIC can induce coughing, chest pain, shortness of breath, skin damage, and eyes, nose, and throat irritation. At more than 20 ppm, injuries are serious and long lasting, with pulmonary or lung edema, vascular hemorrhage, bronchial pneumonia, and death. At 2 to 4 ppm, MIC acts as a potent tearing agent, whereas at 21 ppm, corneas are burned and permanent blindness occurs.

In the 1960s, India was struggling with grinding poverty and a sluggish economy. The country was having trouble feeding itself and maintaining political stability. Understandably, it was with much excitement that the Indian government announced in 1969 that Union Carbide Corporation would build a new agricultural chemicals plant in Bhopal in central rural Madhya Pradesh. Working in close cooperation with the Indian government, which had a one-third ownership, Union Carbide built the plant to make pesticides and fertilizers for India's farmers, who were just beginning to learn and utilize Western agricultural methods. The plant opened on the outskirts of this small (120-square-mile, or 308-km<sup>2</sup>) densely populated metropolitan area, in an economically depressed section, called Jai Prakash Nagar. It employed around 600 people on three

shifts. Encouraged to go to Bhopal by tax and other economic incentives, Union Carbide was originally hesitant to build the plant, in part, because of concerns over an inexperienced workforce.

Once fully operational by the mid-1970s, the plant began to produce pesticides and fertilizers from ingredients made in the United States. By the late 1970s, workforce training and quality control procedures had begun to allow the plant to manufacture products directly from raw materials. In 1980, a new product line was added, a very effective carbamate pesticide called carbaryl, trade-named Sevin. This pesticide was in wide use in the United States. The manufacture of Sevin required large quantities of MIC, and Union Carbide was reluctant to allow its Indian subsidiary to handle and store this extremely hazardous chemical. The majority of their MIC was manufactured and stored at the main plant in Charleston, West Virginia, under very carefully controlled and monitored procedures. Bowing to pressure from the Indian government, which wanted the additional jobs that expanded plant operations would generate, Union Carbide reluctantly agreed to begin MIC formulation and processing at Bhopal.

A MIC production unit was installed along with three partially buried stainless steel storage tanks, each having a capacity of 15,000 gallons (68,000 L). By the end of 1984, the Bhopal plant was losing money. India's agricultural infrastructure was improving, and the need to use expensive fertilizers and pesticides was no longer so urgent. There also was a growing cultural resistance among farmers that was leading to a rejection of Western pest control and cultivation methods.

### THE LEAK AND RESULTING DISASTER

On December 2, 1984, the Bhopal plant reopened after a weeklong shutdown, and at 3:00 p.m., about 100 workers, still upset about their seven-day unpaid vacation, began their usual eight-hour shift. The plant was struggling financially, and, as a result, some important maintenance had been deferred, including on several faulty valves on the MIC tank system. In addition, key experienced managers and staff had been replaced with cheaper, less well-trained personnel. At 9:30 p.m., a shift supervisor ordered a worker to clean a 23-foot (7-m) section of pipe that filtered crude MIC before it emptied into the storage tanks. The worker did so by disconnecting a section of the pipe and connecting a water hose to it. For the next three hours, water seeped past a faulty valve in the line and started to react with MIC in process tank no. 610.

**Children blinded by Union Carbide pesticide leak, Bhopal, India, December 5, 1984** (AP Images)

At approximately 11:45 p.m., workers noticed their eyes were tearing and that the pressure and temperature in tank 610 had risen to more than five times the normal levels. As the heat and pressure continued to build inside the tank, the operational crew and their supervisor took a tea break. At 12:40 a.m., the smell of MIC became overpowering and, half-blind and nauseous, workers started hastily to evacuate the plant. A relief valve then burst, and vaporized MIC shot out of a vent pipe 130 feet (40 m) into the air.

At this point, a series of events began that later caused government investigators to shake their heads in disbelief and the relatives of victims to weep in anger and frustration. As alarms sounded and MIC was pouring out of the stack, the facility's fire brigade arrived to establish a water curtain around the vent and essentially wash or scrub the MIC out of the atmosphere, but their equipment was designed to spray water only up to 100 feet (31 m), and the top of the MIC discharge was 130 feet (40 m) above the ground. A gas scrubber inside the stack, which should have pumped caustic soda into the vent pipe, was turned on. This would have neutralized the

MIC, but it failed to function properly, and no caustic soda was ever released. It was another piece of equipment disabled by deferred maintenance. Emergency tanks intended to contain MIC in case of a catastrophic failure of plant systems could not be used, as they already were full of MIC, instead of being empty, as required by plant emergency procedures. A flare system, designed to burn off escaping gas, could not be activated because a replacement part had not yet arrived from the United States. Emergency sirens sounded to alert nearby residents of a release, but they were turned off by plant operators, who feared a panic. No calls were made to local officials to warn them of the deadly cloud of gas now making its way toward the center of Bhopal, as the outside telephone lines were out of order. One of the last to leave, the plant manager, scrambled over a six-foot- (1.9-m-) high fence, fell, broke his leg, but still found a way to run for his life, leaving no one in charge at the scene. More than 40 tons (36 metric tons) of MIC would be vaporized and released into the air before the reaction burned itself out.

Outside the gates, MIC, trapped underneath a layer of cool winter air and pushed along by a gentle

breeze, flowed downhill toward the sleeping residents of Bhopal. Many awoke briefly, smelled something funny, rolled over to go back to sleep, and died. Others awoke, vomited, found it almost impossible to breathe, and struggled to get outside. Tens of thousands of people filled the streets, all struggling to get away from the toxic cloud that was enveloping their homes and neighborhoods. Many who were now blind were killed by inadvertently staggering in front of speeding cars or buses carrying people desperate to escape. By morning, hospitals were filled and local officials had stopped trying to count the dead. Thousands of bodies filled the streets. By about 3:00 P.M. the next day, most of the gas cloud had dissipated, and recovery efforts began in earnest.

An estimated 3,500 people were killed outright by the gas release, and between 200,000 and 600,000 were injured, many severely. Some nongovernmental agencies and advocacy groups estimated that about 10 to 15 people continue to die every month since the 1984 release of damaged lungs and gastrointestinal systems. More than 7,000 animals were killed, and the local economy suffered losses up to \$65 million.

### THE AFTERMATH

The Union Carbide plant was shut down and operations terminated by the Indian government. Suing on behalf of more than 500,000 victims, the Indian government settled with Union Carbide in 1989 for \$470 million in damages. It also exempted Union Carbide employees from criminal prosecution. In 1991, however, the Indian judiciary accepted the settlement amount but rejected immunity from further prosecution of Union Carbide employees. Warrants were issued for the arrest of Warren Anderson, the chairman, when he and others failed to appear in India to face criminal charges stemming from the release.

Compensation finally began to be paid to victims and their families in 1993, delayed as a result of legal and political wrangling between Union Carbide and the Indian government. By then, the settlement amount had grown to \$700 million. Relatives of the dead received \$3,200 per fatality and more for multiple deaths in the same family. Those seriously injured received \$3,000 each. People who had minor injuries were paid a few hundred dollars. In August 1999, UCC was acquired by Dow Chemical in an \$11.2-billion merger. The combined organizations became the second largest chemical company in the world. In 2001, Union Carbide ceased to exist as a corporate entity.

The Bhopal tragedy sent shock waves through both the business and government communities.

Companies reevaluated their chemical processing and manufacturing operations and instituted much more stringent safety systems. They also rethought site selection criteria before deciding to open a new plant that managed dangerous materials. Regulatory agencies around the world passed stringent new laws requiring companies to disclose the types and quantities of raw materials they stored and handled and to prove that their plant safety procedures were adequate and were being followed. The people of Bhopal paid a terrible price for the several hundred jobs Union Carbide introduced to their community, but the world truly learned a lesson from this tragedy, and the Bhopal disaster ushered in a new era of corporate responsibility and stewardship, especially in relation to developing countries.

### bioaccumulation and biomagnification

In 1948, the Nobel Prize in medicine and chemistry was awarded to a Swiss biochemist, Paul Hermann Muller. Since the early 1930s, Muller had worked on understanding and developing a class of organic chemicals called chlorinated hydrocarbons. In 1939, after systematically synthesizing and testing hundreds of substances, he found that dichlorodiphenyltrichloroethane (DDT) acted as an extremely effective and long-lasting contact insecticide on Colorado beetles, flies, and many other types of insects.

DDT quickly became the pesticide of choice. Inexpensive, safe, very effective, and easy to use, it could be applied directly as a liquid or powder or mixed with oil-based dispersants and sprayed from airplanes, trucks, or hand-held applicators.

DDT helped control the spread of malaria, manage Dutch elm disease, and increase crop productivity, among other benefits. Unfortunately, the extensive and often uncontrolled use of DDT and other chlorinated hydrocarbon-based pesticides exacted a steep environmental price. The main problem with these compounds is that they have the unfortunate tendency to bioaccumulate and biomagnify.

### BIOACCUMULATION

Bioaccumulation is the intake and concentration of a substance in the tissues of a living organism. In itself, bioaccumulation is a normal and important part of the growth and development of all living organisms. In humans, this process allows vitamins A, D, and K; trace minerals; and essential fats and amino acids to be stored in various tissues and organs for later use in metabolic processes. The same mechanisms in the human body that accumulate nutrients and vitamins also work to store synthetic organic chemicals such as DDT.

Bioaccumulation, when combined with DDT's persistence, makes it a deadly environmental contaminant. Once DDT has been applied, it tends to resist such natural destructive processes as photochemical degradation, interactions with other compounds, and biodegradation. It can remain in the environment for a long time without changing. DDT, like other chlorinated hydrocarbon-based pesticides, is a hydrophobic, lipophilic chemical: It is not very soluble in water and tends to move out of solution and into the fat cells of an organism. Water-soluble compounds do not tend to bioaccumulate. Lipophilic substances are not water-soluble and are not easily flushed. They quickly pass through cell membranes and accumulate in fatty tissues. Once DDT is stored in the body's fat, it is not removed, and it does not degrade. As additional DDT-contaminated fat reserves are added, the amount of DDT increases or bioaccumulates, and, when those fat reserves are eventually used, appreciable amounts of DDT are remobilized into the organism.

Bioaccumulation does not occur at the same rate in all species, or even in individuals within the same species. Animals that are big or fatter tend to bioaccumulate at higher levels than short-lived, small, or slender species. An old trout probably has bioaccumulated more DDT than a young bluegill from the same lake. DDT has been detected in human fat and the milk of nursing mothers. DDT also interferes with eggshell production and was responsible for the near-extinction of the bald eagle, California condor, and other birds. Birds exposed to DDT laid eggs with very thin shells that cracked and broke during nesting.

### EFFECTS OF BIOMAGNIFICATION

DDT enters an organism through biological activities that are collectively known as uptake, or exposure mechanisms. These include inhalation of dust and vapor, ingestion of plants or soil contaminated with DDT, or absorption through the skin, feathers, fur, scales, or gills. Once inside an organism, DDT begins to biomagnify. Biomagnification results in the accumulation of a substance in an organism at higher levels than are present in its food supply or surrounding environment. It most commonly occurs as DDT moves up through the trophic levels of a food web. One study of DDT's biomagnification ability found that when concentrations were 10 parts per million (ppm) in the soil, they reached more than 140 ppm in earthworms and more than 400 ppm in robins.

### RECOGNITION AND REGULATION

Although it may seem obvious that pesticides and perhaps other industrial chemicals could bioaccumulate and biomagnify, the possibility was not widely considered during their development and use. That changed in 1962, when *Silent Spring* was published by Rachel Carson. The book carefully and irrefutably documented how DDT and other organochlorinated pesticides entered and worked their way up the food web. Carson's *Silent Spring* is often credited as awakening in the general public an awareness of society's use of chemicals and beginning the modern American environmental movement. Sadly, Carson died of breast cancer two years after *Silent Spring* was published and never saw the wide-reaching effect of her work, not only in the United States but around the world. DDT was banned for sale in the United States in 1972, although it is still manufactured for export to other countries.

DDT is not the only industrial chemical that bioaccumulates and biomagnifies. Like DDT, persistent organic pollutants (POPs) are difficult to degrade and are mobile in the environment. The U.S. Environmental Protection Agency (EPA) recognizes 12 POPs, many of which occur as semivolatile compounds: aldrin, chlordane, DDT, dieldrin, endrin, heptachlor, toxaphene, Mirex, hexachlorobenzene (HCB), polychlorinated biphenyl (PCB), dioxin, and furans. Semivolatile POPs can exist as either solids or vapors, depending upon the temperature. Once in the environment, if the temperature is warm enough, POPs such as PCBs or toxaphene evaporate or are carried on dust particles, their distribution being controlled by atmospheric processes. As the temperature cools or the dust settles, the POP can have traveled thousands of miles from

**Illustrated graph of time and bioaccumulation versus biomagnification. Certain chemicals such as DDT and many inorganic elements accumulate in the tissue of fish through ingestion. As fish eat more tainted food over time, more contaminants accumulate in their fatty tissues. This is shown by larger darker areas on the fish toward the right reflecting bioaccumulation. Predators preferentially eat the tainted fish and primarily tissue and organs that contain the contaminants. The higher the predator in the food chain, the more concentrated the contaminant in the body tissues through biomagnification.**

where it was originally released. It is this “grass-hopper effect,” the cycle of evaporation coupled with windblown transport of contaminated dust, settlement, and then remobilization, that results in the worldwide distribution of POPs, with their presence often detected in areas where they have never been used. DDT has been found in arctic ice and PCBs have been reported in the tissues of deep ocean Atlantic cod.

Organochlorinated pesticides and other POPs are being addressed under the EPA’s Persistent Bioaccumulative and Toxic (PBT) chemical program. Action plans have been developed for most of them, and procedures are being implemented to ban their manufacture and use and to track their presence in the environment.

**bioremediation** In some cases, usually because of the physical difficulty in excavating pollution, undue risk if the material is exposed to the environment, or cost-effectiveness, the best method of degrading or removing pollution from soil or water is to let plants or microorganisms do the work. Although in the environmental industry bioremediation is an advanced technology, it actually takes place all the time in all but the most extreme of climate conditions. Bioremediation is the action of microorganisms, fungi, green plants, or their enzymes to remove pollutants and restore the environment to its natural state. All decay of materials, from moldy bread and spoiled food to compost piles, is accomplished by living organisms. Bioremediation is just directed decay and chemical transformation to remove or neutralize contaminants. Typically, if

plants are the vehicles to remediate the problem, the method is termed phytoremediation. There are also several other subcategory terms and processes in bioremediation, such as biostimulation, bioaugmentation, bioventing, biotransformation, and others that are all part of the bioremediation processes.

Bioremediation is quite a complex science requiring expertise in microbiology, chemistry, and geology for effective use. Typically, a specialist will evaluate the pollution and then choose the most effective microbes to degrade the contaminants. In some cases, the existing microbes in the soil are sufficient to do the job, and the remediation method is called *natural attenuation*. In other cases, conditions must be changed to increase the activity of desired microbes. Air can be pumped into the soil to help aerobic organisms flourish at the expense of anaerobes. Nutrients can also be pumped into soil to help the microorganisms flourish and speed the process. In some cases, the soil is removed and bioremediation is performed *ex situ*. Depending upon the type of pollutant to be removed and the physical situation, different techniques can be employed.

#### ORGANIC POLLUTANTS

It was observed during the first major ocean oil spills in the 1960s that bacteria flourished in the oil and degraded it relatively quickly. These observations are the basis for bioremediation of organic pollutants. In most cases and especially with organic pollutants, bacteria are the best choice for cleanup. Many bacteria under certain conditions of temperature, pH, and soil chemistry are effective as degraders of specific pollutants. Air is commonly pumped into the soil contaminated with organic pollutants to stimulate the microbes so that they will reproduce faster and flourish, thus removing the pollutants more quickly. In some cases, nutrients such as methane, phosphorus, or nitrates are also added. New bacteria may need to be introduced into the soil with or without stimulation methods. When multiple organic pollutants are present, a cocktail containing a mixture of microbial species must be introduced into the area under any number of stimulation techniques to address the pollution problem. The progress of pollutant degradation by the bacteria must be carefully monitored and adjusted as needed.

The bioremediation of organic pollutants involves the bacteria actually dissociating the compounds into other less dangerous compounds, ideally water and carbon dioxide. This is especially useful for organic solvents in situations where pump-and-treat technologies or air stripping are insufficient. The bacteria consume the carbon and other elements as

food. Bioremediation of organic pesticides, however, is not as easy. Many of these pesticides are toxic to bacteria, which cannot function in such a toxic soil environment. In these cases, the pollutant may be very persistent. Dichlorodiphenyltrichloroethane (DDT), for example, can persist in soil for decades because no appropriate microorganisms can survive in it.

### INORGANIC POLLUTANTS

Bioremediation can also be used on inorganic pollutants in some cases, but it is less common. The inorganic pollutants of interest primarily include heavy metals and radioactive elements. Unlike organic pollutants that can be readily changed into common nontoxic substances, inorganic pollutants cannot be degraded. However, the oxidation state of some heavy metals can make them more or less dangerous. For example, hexavalent chromium (+6) is far more dangerous than trivalent chromium (+3). Certain bacteria can change the valence state of heavy metals and allow them to form complexes with other, less dangerous properties. These properties may be that they are less toxic, insoluble, and fixed in the soil or soluble and able to be leached from the soil. There are several problems with bioremediation of metals. In some cases, microbes can actually make the metal more toxic. Mercury is a toxic heavy metal, but it is many times more toxic if it is methylated. Methylated mercury is formed by microbial activity in the natural environment, typically lakes and wetlands. The second problem is that heavy metals are commonly immobile in the soil where they are deposited. Microbial action can complex them into compounds that can be ingested by other organisms. This action allows heavy metal to enter the food chain, where it can do even more damage because heavy metals tend to bioaccumulate and biomagnify.

In some cases, heavy metals and radioactive elements may be removed through phytoremediation. Plants have the ability to partition out certain elements, allowing some into their systems while blocking others. There are certain plants that readily take in heavy metals and radioactive elements. These plants can be grown on tainted soil and actually remove the unwanted elements with time. The problem is what to do with the contaminated plants once they are harvested. Burning them transfers the pollutant into the atmosphere, where it can be inhaled or wind up as fallout and pollute some other area. A good plant for phytoremediation of heavy metals and radioactive elements is tobacco. This is one of the reasons that tobacco smoke is so deadly; it is rich in these inorganic elements.

### GENETIC ENGINEERING

Certain bacteria have bioremediation abilities that others do not. Some bacteria that are excellent at bioremediation may be rare or only able to thrive in conditions that do not characterize common polluted areas. The desirable traits of these inappropriate bacteria may be transferred to more commonly occurring bacteria through genetic engineering. Desirable traits may include enhanced tolerance to adverse conditions or chemicals, ability to reproduce faster, ability to thrive in aerobic or anaerobic conditions as need dictates, ability to dissociate organic compounds, or ability to change the valence state of metals and complex (fix) them into minerals, among others. Genetically enhanced common bacteria can then be introduced into the polluted area to enhance cleanup. Genetic engineering is no easy task and may require huge amounts of laboratory experimentation and sequencing to produce the enhanced bacteria if transfer of the desired trait or characteristic is possible at all. There is also a risk of accidentally introducing unwanted traits into common bacteria that may create other problems. Nonetheless, genetic engineering of plants and organisms to produce quicker and more complete remediation is the wave of the future.

**Blake & Johnson Company Beaufort, South Carolina May 1975 Water and Soil Pollution** In the 1980s, the Blake & Johnson Company (B&J) was one of the largest manufacturers of nails and fastener systems in the United States. As

part of its production process, B&J coated steel, brass, or iron products by passing them through a series of plating tanks that contained various metals such as chromium, zinc, cadmium, and nickel, among others, dissolved in acid. Coating or plating allowed the screws, nails, and other fasteners to be used in a variety of outdoor and corrosion-resistant industrial and commercial applications such as roofing or on boats.

### THE ENVIRONMENTAL PROBLEM

Between 1969 and 1980, B&J discharged approximately 30,000 gallons (120,000 L) per day of plating wastewater into an unlined infiltration lagoon on their 25-acre (4,166-m<sup>2</sup>) property in Beaufort, South Carolina, about 35 miles (56 km) south of Hilton Head. In May 1975, a small section of one of the lagoon's walls failed, and some wastewater was released into an adjacent drainage ditch. The company reported the spill, and subsequent sampling by the South Carolina Department of Health and Environmental Control (SCDHEC) found cadmium and chromium contamination in the surface water and sediment of this drainage channel. Although the release apparently was a one-time event, SCDHEC began a series of groundwater investigations at the site that included the installation of monitoring wells screened at various depths in the aquifer underlying and surrounding the lagoon.

Several of the groundwater samples collected from these wells, as well as other wells installed and sampled later, contained chromium, lead, iron, and mercury at concentrations in excess of drinking water standards. Despite these results, in 1980, the Industrial and Agricultural Wastewater Division of SCDHEC advised B&J, "We have recently completed evaluation of groundwater at Blake and Johnson with favorable results," and "there is little likelihood of finding serious contamination of groundwater." The U.S. Environmental Protection Agency (EPA) seemed to concur when, in May 1981, it released a report stating that "no action (was) needed" at the site. In November 1981, a SCDHEC interagency memo from the Ground Water Protection Division disagreed with the EPA and the Agricultural Wastewater Division conclusions and stated that, because the site is in a major aquifer recharge zone, they had serious concerns about B&J's waste disposal practices and that previous SCDHEC findings were "not consistent with our assessment of the situation."

Beaufort County is made up of about 70 islands connected by a complex series of inland and coastal estuaries and other waterways. It is a sensitive envi-

ronmental setting where tourism, recreation, and fishing are major sources of revenue. The county is home to several resorts including Hilton Head, noted for their pristine beaches and clean water. Whereas the majority of potable water for the area is provided by the Savannah River, groundwater is an important secondary, or backup, water supply in the site vicinity for both private and municipal uses.

Beaufort's Burton Well Field, approximately 2.5 miles (4 km) southeast of the B&J site, is used to supplement peak water demands between May and September (tourist season). In addition, the nearby Marine Corps Air Station and the Laurel Bay Naval Housing area rely on well water as backup supplies. A few local industries also use well water in their manufacturing operations. Most of these wells are completed in the deep Floridan Aquifer, found several hundred feet below the surface, and therefore are unlikely to be affected by operations at B&J. The presence of the cadmium, chromium, and lead in surface water and soil samples, however, was troubling for a community that was so dependent upon its water resources for prosperity and quality of life.

For business reasons not related to environmental issues, B&J ceased operations in 1980, and its successor (Independent Nail Company) changed the nature of site operations so that there were no wastewater discharges to the lagoon. During its operational life, B&J released approximately 85 million gallons (345 million L) of plating wastewater into the lagoon or surface impoundment, and some of this wastewater infiltrated into the groundwater system. Upon the basis of additional environmental investigations by the EPA and the state of South Carolina, which uncovered further soil and groundwater contamination on the property, and as a result of both discharges to the surface impoundment and generally poor handling of hazardous materials, the B&J property was added to the National Priorities List in 1984 and became a Superfund site. The investigations found chromium, cadmium, nickel, and zinc in soil samples from the B&J site at concentrations ranging from hundreds to tens of thousands of times above background or ambient values. Fortunately, this contamination was primarily confined to the upper one to two feet (0.31–0.62 m) of soil across the site and in the surface impoundment. This made cleanup much easier.

### CLEANUP OF THE SITE

The EPA selected soil stabilization and solidification as the preferred remedial technology for the B&J property. In contrast to incineration, the stabilization and solidification process does not destroy or

reduce the toxicity of the contaminant mass. Rather, it inhibits or prevents the release of contaminants to the environment and lessens the likelihood of human exposure. Soil stabilization and solidification most commonly is used for soil contaminated with metals, as its effectiveness on organic compounds has been inconsistent. There are two basic approaches used in solidifying and stabilizing contaminated soil, chemical-based systems and thermal-based systems.

### Chemical Based Systems

The solidifying and stabilizing agent traps contaminants in place, preventing leaching as water infiltrates through the stabilized mass. By far, the most common compounds used in chemical solidification systems are pozzolanic materials. These are inorganic, fine-grained, siliceous or siliceous and aluminous dustlike materials that do not form hardened cement. Pozzolanic materials also do not allow mortar and cement to cure or set too rapidly and increases its durability. The use of pozzolamics also has the added benefit that as the hazardous contaminants are encapsulated, the physical properties of the soils are changed. The soil's load-bearing capacity (strength) is increased, and its permeability is reduced, making it ideally suited for use as backfill for excavation.

Soil from the B&J property and the bottom of the lagoon was excavated and mixed into slurry with a sodium silicate (pozzolanic)/cement-based material. It was then pumped into a surface impoundment as backfill. The resulting material was a claylike substance that had a high bearing strength and solidified within 72 hours. After it hardened, six inches (15.2 cm) of topsoil was spread and grass seed was planted over the former lagoon area. Approximately 6,200 cubic yards (5,283 m<sup>3</sup>) of soil was treated in this way at the relatively low cost of about \$1.2 million, or \$194 per cubic yard.

The effectiveness of soil solidification/stabilization was assessed through a long-term monitoring program using a laboratory test known as Toxic Characteristic Leaching Procedure, or TCLP. In 1990, the EPA required that TCLP be used to simulate leaching conditions in a landfill in the presence of putrescible waste (garbage). This test also is used to identify whether a waste has certain hazardous characteristics. A sample of the B&J solidified and stabilized soil was pulverized and passed through a 0.37-inch (95-mm) screen. A sample of 0.22 pound (100 grams) of the material was then placed in a special container, called an airtight zero head extraction (ZHE) device, mixed with acetic acid, and agitated. The solution was then extracted from the ZHE container, filtered, and tested. If contaminants

are not detected in the solution above regulatory limits, then the waste is stabilized and is considered nonhazardous.

**Boston Molasses Disaster** *Boston, Massachusetts January 15, 1919* *WaterPollution* Environmental disasters do not always have to involve toxic substances. Sometimes, they just involve too much of a substance that is harmless in small quantities. This is the case with the Boston Molasses Disaster, or "the Great Molasses Flood," as it is also known. This was almost a defining event in the history of the city of Boston. For decades afterward, Boston smelled of molasses to the point where it was part of the character of the city. The event was celebrated in schools every 10 years on the anniversary for many decades. As with most disasters, it was the location and timing that made the Boston Molasses Disaster such a defining event.

### THE SETTING

A large molasses tank was built on the North End of Boston, Massachusetts, in 1915, by the Purity Distilling Company. The tank was 58 feet (17.8 m) high and 90 feet (27.7 m) wide, made of cast iron

plates that were sunk into a concrete base and riveted together. The tank was built to hold up to 2.5 million gallons (11.4 million L) of molasses, which was distributed to produce rum, baked beans, and industrial alcohol. Perhaps because they sensed the inevitability of Prohibition, the Purity Distilling Company sold the tank and entire complex to United States Industrial Alcohol in 1917, which produced alcohol for industrial uses only. The area around the tank was industrial and quite active. There were freight sheds of the Boston and Worcester and Eastern Massachusetts Railways, the paving division of the public works department including more than a dozen horses, the headquarters of Fireboat 31, the Charlestown Navy Yard, the wharves on the Charles River, the Boston Gaslight Building, and a residential area, all under a section of the elevated railway.

### THE EXPLOSION AND FLOOD

On January 12, 1919, the temperature was a frigid 2°F (−16.7°C) in Boston, and people stayed indoors as much as possible. A warm front passed through the next day, and the temperature rose quickly to unseasonably high temperatures. By January 15, it had reached 43°F (6°C), and the people of Boston began to spend as much time as possible outdoors. At noon on the 15th, rather than seeking shelter, many of the workers in the industrial area between Copp's Hill and the Charles River chose to eat their lunches outdoors, and children went home for lunch or played in the North End playground.

Without warning at 12:30 p.m., a deep, low rumble shook the area, followed by a heaving of the ground beneath the feet of the stunned people. This was immediately followed by the sound of ripping and tearing of steel and rapid popping like machine gun fire, as the tank rivets broke away. One plate shot away from the tank with such force that it sheared off the lower support for the elevated railway. Other flying plates and rivets tore apart the buildings all around the square. Then a booming roar pierced the air as the bottom of the tank split wide open, and a geyser of yellow-brown liquid shot skyward followed by a huge wave of molasses.

The tank had been filled just two days before to a height of 49.5 feet (15.2 m), so that it contained 2.3 million gallons (10.4 million L) or 14,000 tons (12,727 metric tons) of molasses. As the wave of molasses emerged from the tank and onto the open area, it was 15 feet (4.6 m) high and traveling at 35 miles (56 km) per hour. As it moved, it exerted a forward pressure of two tons per square foot (1,814 kg/m<sup>2</sup>) that literally crushed most buildings that it hit, and, after it passed, it created a vacuum that was

strong enough to destroy the remaining structures and pulled objects into it. The molasses flowed with a hissing and sucking sound as it destroyed everything in its path. Those people who were not killed in the initial explosion were pulled into the molasses, which was so viscous that victims simply sank into it and disappeared no matter how hard they struggled. The horses at the public works department were sucked in and crushed or drowned, as were the people. It knocked out the support for the elevated railway, and the tracks slowly sank down. The alert engineer of an oncoming train saw the tracks begin to sag and braked the train in a panic. It stopped in time to see the sagged part of the tracks disappear into the molasses flood. The train went off the track, but its passengers were safe.

As the wave hit the freight offices, it was still five feet (1.5 m) high. It crushed the doors, windows, and some of the facing walls and crushed the goods and the clerks who were working there. The molasses was so heavy that it collapsed the floor, crushing and drowning the workers in the basement. Some who survived the initial collapse tried to run up remaining stairs, but all the molasses had to do was engulf the ankles of the victims to trap them. It was so thick and sticky that it immobilized the victims' legs upon contact, and they helplessly disappeared into the gooey mess no matter how much force they exerted with their muscles.

The wave picked up the loaded freight cars and propelled them like missiles through buildings and ultimately crushed them as well. It knocked over the firehouse and carried it toward the sea. The wave continued into the residential area, as well, crushing and carrying away houses and anything else in its way. The wave washed over the Boston streets during the school lunch hour, and a number of young students, having gone home for a quick snack or sandwich, were on the streets. Several of them were also engulfed and killed. The wave thinned as it spread out but could not flow up the hills to the south and stopped after the short few minutes of terror it had inflicted.

### RESCUE AND RELIEF EFFORTS

A policeman in the area was calling headquarters at the time of the explosion and reported the disaster as it was happening. The first alarm to the nearest surviving fire station went out at 12:40 p.m., just 10 minutes after the explosion. Every form of rescue equipment was raced to the scene from all over the city. Once they arrived, however, the task of rescuing anyone from the thick standing molasses was not easy. The first arrivals were 116 sailors from the light

ship *USS Nantucket*, training vessel that was docked in the harbor, but they could only rescue people at the edge of the flood. Next the Boston police, Red Cross, army, and other navy personnel arrived but had the same trouble reaching people. Finally, the Boston firemen laid ladders horizontally out over the molasses and crawled out on them in an effort to pick up the injured, dead, and dying. Fifteen bodies were recovered that day and another six would be recovered over the next three days for a total of 21 fatalities. The last two bodies recovered, three days later, were so battered and crystallized in the molasses that they could not be identified. There were also 150 injuries caused by the disaster. Many of these people were quickly taken to nearby hospitals by whatever means available. There were so many injured people, however, that several doctors set up a makeshift treatment center in a nearby building.

### THE CLEANUP

As the people of Boston tried to clean up the two to three feet (0.5 to 1 m) of standing molasses that covered a significant part of the downtown area, it quickly became obvious that it would be no easy task. Firemen hosed down buildings to wash them off, a miserable job in the cold January weather. Fireboats sprayed saltwater on the streets in an effort to remove the molasses, but the spraying caused it to froth up into a yellow foam that just spread it farther. That which was washed into the harbor turned the water brown, and a sticky film coated all ships and boats that passed through. Sand was dumped on all of the molasses that remained. About 87,000 hours were devoted to the cleanup. Ironically, on the night of January 16, the cleanup was halted when all the church bells in the area began ringing to proclaim that Nebraska had just cast the deciding

Devastation caused by the explosion of a molasses storage tank in Boston, Massachusetts, January 15, 1919—in the background is Charlestown Navy Yard (AP Images)

vote on the Eighteenth Amendment, and Prohibition became law.

Cleanup did not proceed as smoothly as desired. All the rescue workers, cleanup crews, local workers, and residents, and droves of sightseers walked through the molasses, sand covered or otherwise. The molasses on their boots was spread over the rest of Boston and out into the suburbs. Everything in the city was sticky, from streetcar seats to public telephones to the floors of every store and public building. It was even reported to have spread as far away as Worcester, Massachusetts. The smell of molasses lingered in Boston for years.

### LAWSUITS

There were about 125 lawsuits filed against the United States Industrial Alcohol Company for damages and wrongful deaths. It was the longest set of hearings for a single case ever in the history of the Massachusetts courts, lasting about six years. There were so many lawyers that they could not all fit into the courthouse, so two were chosen to represent all of the claimants. There were more than 3,000 witnesses, many of them expert witnesses, giving 45,000 pages of testimony. Never in the history of New England had so many engineers, metallurgists, and scientists been asked to testify. One structural engineer testified for three weeks straight, several times until 10 in the evening. In the end, it was decided that the “factor of safety” was too low in the incident, and the United States Industrial Alcohol Company was held liable. The actual cause of the explosion was fermentation in the tank, causing excessive pressure that exceeded the strength of the tank. The warming weather accelerated fermentation. The company paid a little less than \$1 million in damages to settle all of the claims or about \$12.1 million in 2009 dollars. It is reported that families of those killed received about \$7,000 apiece, about \$85,000 in equivalent 2009 money.

### Braer oil spill Shetland Islands, Scotland January 5, 1993 Water Pollution

In 1975, at the Oshima Shipbuilding Company in Nagasaki, Japan, the keel was laid for a single-hull, oceangoing tanker with a deadweight tonnage–cargo capacity of about 100,000 tons (90,000 metric tons), or approximately 25 million gallons (114 million L). Measuring 780 feet (240 m) long and 130 feet (40 m) across, the ship was built to cruise at 14 knots and equipped with the most up-to-date navigational aids and control systems. Delivered as the *Hellespont Pride*, the ship performed adequately and was sold in 1989 to Bergvall & Hudner (B&H), a Norway-based shipping company. It was one of some 15 ships in this company’s growing fleet that were purchased with the proceeds of an initial public offering. Renamed the *Braer* (an acronym of the two owners’ names), it was registered in Monrovia, Liberia, and chartered to Ultramar, Ltd., a Canadian oil company. On January 3, 1993, the now almost-20-year-old tanker picked up a cargo of 93,170 tons (84,700 metric tons) of light North Sea crude oil from a refinery and terminal at Mongstad, Norway. Bound for Canada, the *Braer* planned to sail westward, through the North Fair Isle Strait, across the North Sea, eventually berthing at Quebec to off-load.

### THE ACCIDENT AND SPILL

Ocean conditions in the North Atlantic in early January are characterized by gale force winds, bitter cold temperatures, and very rough seas. The experienced crew of the *Braer* was prepared for the voyage, obtaining current weather forecasts and having made this or similar trips many times. Clearing the Mongstad harbor, the *Braer* immediately was buffeted by strong southerly winds, and during the early morning hours of January 4, as a result of the pitching and yawing of the ship, several pieces of spare steel pipe tore loose from their straps and began rolling around the port side of the deck, crashing into the engine casing. The crew eventually secured the pipes and inspected the engine casing for damage, but did not find any.

As with many ships of its generation, the *Braer* was fueled with a heavy No. 6 fuel oil also called Bunker C. This oil was so viscous that it needed to be heated to thin it out for use in the ship’s engines, which turned the *Braer*’s single propeller. An auxiliary, or supplemental, boiler was used for this purpose. During the evening of January 4, the auxiliary boiler was taken off-line for routine adjustments. Once these were completed, the crew was unable to restart it. Without the auxiliary boiler, the Bunker C

**Oil-covered cormorant killed as a result of the tanker *Braer* running aground and leaking off Garths Ness, Shetland Islands, Scotland, 1993 (Ian Cook/Time Life Pictures/Getty Images)**

could not be used, so the engine room crew switched to its backup system of thinner, No. 2 diesel fuel.

Around midnight, the crew found that seawater was present in the oil supply line to the boiler, thus preventing the auxiliary boiler from relighting. As they attempted to drain the seawater and relight the boiler, seawater also was found in the oil supply service line to the main engine and generator, which powered the ship's electrical systems. Shortly before 5:00 A.M., the main engine stopped, fouled by seawater in its fuel. A few minutes later, the main generator shut down, and the ship was floating in heavy seas with only minimal lighting and radio control systems working off emergency batteries that were quickly being drained.

The ship was drifting northward under an unrelenting force 10 southern wind, which included 20–30 foot- (6–9 m-) high waves with overhanging crests, a white sea with densely blown foam, and heavy rolling. The position of the *Braer* when the engines failed was 10 miles (16 km) south of the Shetland Islands. These are Scottish territories of the United Kingdom, lying about 100 miles (160 km) northeast of the Scottish mainland. The Shetland Islands are made up of about 100 islands, 15 of which are inhabited. The sea dominates the Shetlands culture. Fishing and tourism are vital parts of this small archipelago's economy. Alerting the Scottish Coast Guard, the *Braer* called for a tow, but by early morning the ship had moved to within four miles (6.4 km) of Sumburgh Head and was in danger of grounding. Through a series of dangerous maneuvers, most of the 34 crew were evacuated by helicopter, while the captain and some engine room staff volunteered to remain onboard to try to restart the engines, boiler, and generator. By midmorning,

the *Braer* had drifted to within 0.5 mile (0.8 km) southeast of Horse Head Island, and the rest of the crew was taken off by helicopter.

By now, two seagoing tugboats had arrived and attempted to secure towlines, but the rough seas and the fact that no crew remained on the *Braer* to help fasten the lines made it impossible. Miraculously clearing Horse Head Island, thanks to a strong westward tide, the *Braer* once again began to drift north, and a party of volunteers, including the captain, were dropped onboard to try to attach messenger lines shot over from the seagoing tugboats. Messenger lines, also called shot lines, are thin cables that are propelled by pneumatically fired cannon or cylinders from the tug onto the deck of the disabled vessel. One end of the messenger line is connected to a thick towing cable, and the crew of the disabled vessel attaches the other end to a manually operated winch. The winch then is used to haul the towing cable aboard the disabled vessel, where it is fastened to special deck cleats or the ship's heavy mooring lines. After the two vessels are joined by the cable, the disabled ship is taken in tow.

While the volunteer crew struggled to receive and attach the messenger lines, at one point almost being able to make the critical connection before the raging sea tore the line from their hands, the *Braer's* luck finally ran out and it went aground on the west side of Garth's Ness at approximately 11:20 A.M. on January 5, 1993. Oil immediately began to gush into the sea and, fearing a fire or explosion, the coast guard ordered the ship abandoned.

The *Braer* was fully loaded with Gulfaks crude oil. In Europe, crude oil is priced on the basis of comparison of its physical characteristics to reference oil. Brent crude, or oil from the Brent oil field in the North Sea, is the benchmark against which oil from all other North Sea oil fields is measured. Gulfaks crude is light (low-density) oil from a well-developed field in the North Sea near Norway. This type of oil is more easily dispersed and broken up than some other types of thicker, heavier North Sea crudes. Over the next 12 days, as the large waves and overpowering winds relentlessly pounded the *Braer*, the ship broke into three pieces and the entire cargo and onboard fuel supply were discharged onto the coast of Garth's Ness, near Scalloway, the busiest fishing port in the Shetlands. Approximately 1,650 tons (1,500 metric tons) of Bunker C, the fuel used to power the ship's engines and generator, also was released as a result of the grounding.

The *Braer* disaster was the 11th largest oil spill in maritime history. Later investigations by the *Braer's* owners and insurers, as well as the Scottish government, found that the air intake pipes inside

the engine casing were damaged when spare steel pipes broke loose in the heavy seas and repeatedly smashed against the side of the engine compartment. These broken intake pipes allowed seawater to enter and contaminate both the diesel fuel and Bunker C oil supplies.

### THE CLEANUP

The heavy seas and high winds prevented the use of skimmers or other types of mechanical oil collection devices, and even chemical dispersants were used only on a limited basis. The roiling seas and blustery winds acted to break up and volatilize the light crude oil as it poured out of the hull of the *Braer*. So intense was the weather that a measurable oil slick never formed and the floating hydrocarbon was quickly dispersed or mixed within the water column. Typical seawater contains oil at concentrations of around three parts per billion. Within the immediate vicinity of the *Braer*, as oil was emptying into the sea, ocean-water samples contained concentrations of petroleum hydrocarbons in the hundreds of parts per million. As the oil dispersed, hydrocarbon concentrations dropped to 50 ppm, still several thousand times higher than normal. Even two weeks after the spill, oil was present at around 4 ppm.

Subsequent studies found that much of the released oil attached to sediment stirred up by the gale. These oil-laden sediments were widely redistributed by sea-floor currents but generally tended to accumulate in two natural topographic low spots near where the *Braer* had gone aground. The oil contaminated shellfish, and a Fisheries Exclusion Zone was established along much of the coastline, preventing exploitation of this important local resource for several years. The prohibition against commercial fishing in these areas was not lifted completely until 2000.

On land, a small but dedicated band of volunteer and paid professionals struggled to rescue seabirds that had become coated with oil. They also conscientiously removed contaminated seaweed and oily debris. Some 1,500 dead and oil-covered birds eventually were found on beaches near the *Braer*. Several thousand “farmed” salmon, trapped in special submerged pens just off the coast, bore the brunt of the damage. Contaminated beyond salvation, they either died in their cages or were ordered destroyed by local health officials. Ten seals were oil-covered and their bodies found on the beach. A pair of otters survived oiling but were crushed by a news van as it rushed to cover the effects of the spill on local wildlife. Adjacent to the grounded ship, roads, farmlands, and even sheep became coated with oil as onshore breezes blew droplets inland.

### THE AFTERMATH

The 1993 tourist season for the Shetland Islands disappeared along with the *Braer*'s oil. More than \$4 million in travel, hotel, and tour bookings was cancelled and more than 200 compensation claims were filed for losses related to business interruption as well as property and livestock damage. Several health-related claims also were made, but most government studies found that health impacts were primarily minor and short-lived. Total claims, including insurance claims for the vessel and its cargo, exceeded \$100 million.

The transport of oil over the oceans is a vital part of the world's economy and a key factor in maintaining a reliable energy supply and a strong national defense for many countries. It also can be risky, and no corporation is willing to invest millions of dollars to build a tanker and operate it unless insurance is available. After the *Torrey Canyon* disaster, insurance companies became less willing to provide coverage for the large “supertankers” that were being built. Without insurance, the global transport of oil would either cease or become prohibitively expensive. The International Maritime Organization, or IMO, recognized this developing crisis and convened the 1969 Civil Liability Convention (CLC), which limited the financial liability of both shipowners and insurers for the consequences of an oil spill. The CLC clearly holds the owner of the ship responsible for the cleanup of any oil that escapes from its vessel but limits claims for damages on the basis of the vessel's cargo capacity. Signatory countries to the CLC must require oil-carrying vessels with a cargo capacity of more than 2,200 tons (2,000 metric tons) that operate in their waters to carry certain levels of insurance. If it can be demonstrated that the shipowner acted recklessly or did not take reasonable precautions to prevent the spill, then the liability is not limited.

To provide compensation when damages are in excess of the limit of liability established under the CLC, an injured party can make a claim against the International Oil Pollution Compensation (IOPC) Funds. These three funds, the 1971 Fund, the 1992 Fund, and the Supplementary Fund, were set up to help pay for property damage, including cleanup costs, incurred when oil is unintentionally released from a ship. The claim is paid from one of the designated funds to the injured party depending upon the extent of the damage and whether the damage has occurred in a country that participates in the IOPC process.

Based in London, the IOPC Funds are financed by surcharges on certain types of oil transported in oceangoing vessels. They essentially are a tax or levy

on every gallon of oil that is paid by the terminal or refinery that receives the tanker-delivered product. For damage by a seaborne release of oil, governmental agencies, private citizens, or businesses may file a claim for compensation with IOPC. The 1969 CLC set a limit of liability on the *Braer's* owners for pollution damage and cleanup costs of \$8 million. Spill victims also were able to file claims with IOPC. In total, about \$80 million was available as a total compensation pool for those damaged by the *Braer's* release. By 1996, most claims had been settled and total payouts by both the *Braer's* insurers and IOPC were in the range of \$50 million.

**brownfields** Certainly the goal of any environmental remediation project is to produce a "green field," in which all pollutants are removed and the land is restored to its prepollution productive state. In many cases, the cost of remediation and subsequent monitoring is so prohibitive that it is more cost-effective for companies and individuals just to pay the taxes on the affected property, fence it off, and let it lie fallow indefinitely. Many such sites are within thriving urban areas and form a blight on the community, slowing economic growth by suppressing property values and sequestering valuable land that could otherwise be a thriving business. The U.S.

Environmental Protection Agency (EPA) recognized the problem and in 1995 devised a program to allow companies and communities partially to restore severely polluted property, called brownfields. The program is, therefore, a compromise economic redevelopment program for polluted properties. The official EPA definition of brownfields is

a property, the expansion, redevelopment, or reuse of which may be complicated by the presence or potential presence of a hazardous substance, pollutant, or contaminant.

If the site under consideration meets the criteria of severe pollution under several federal designations such as the Solid Waste Disposal Act, Federal Water Pollution Control Act, Toxic Substances Control Act, or Safe Drinking Water Act, it can be partially restored to meet certain purposes. It may never be a park or a playground, but it can be a parking lot, a warehouse, or even a manufacturing plant for certain industries. To accomplish this restoration, the more toxic of the pollutants must be removed and the rest reduced to acceptable levels for the proposed purpose. The property must be inspected and pass certain remediation criteria before any redevelopment can take place. It also must be monitored for the life of its use.

The idea of brownfields legislation is that it encourages at least the partial remediation of otherwise highly and indefinitely polluted properties. It increases the local tax base, facilitates job growth, utilizes existing infrastructure, reduces development pressures on undeveloped open land, and ultimately improves and protects the environment. It is a method for urban renewal in older cities with an industrial heritage. The EPA estimates that there are more than 450,000 brownfields in the United States. As a result of the Small Business Liability Relief and Brownfields Revitalization Act, the program includes significant funding in the form of grants including assessment grants to evaluate the potential problem, revolving loan fund grants to aid in actual remediation, job training grants for environmental training of the community, and cleanup grants for direct remediation of properties with planned non-profit use. The brownfields program has many individual success stories but in general has leveraged more than \$6.5 billion in brownfields cleanup and redevelopment funds from a variety of sources, leading to the creation of more than 25,000 new jobs.

Examples of success stories in the brownfields program are plentiful. Through a \$200,000 EPA Brownfields Pilot grant to the city of Dallas, Texas, in September 1995, more than \$550 million in

Former Bethlehem Steel plant, now a brownfield in Pennsylvania (Christopher Russo; used under license from Shutterstock, Inc.)

public and private funding was leveraged toward cleanup and redevelopment of polluted areas in low-income neighborhoods. More than 900 jobs were created through brownfields cleanup and redevelopment efforts that included the construction of a housing complex and a shopping center, among others. Glen Cove, New York, received a pilot grant from the EPA to redevelop its run-down waterfront area. The grant helped the city leverage approximately \$20 million in grants and assistance from various government agencies. As a result of this improvement and commitment, private development invested in renewal of a number of properties along the waterfront. The city's overall Revitalization Project is generating almost \$200 million in annual sales and \$10 million in taxes and created more than 1,700 jobs. In Clearwater, Florida, a \$200,000 grant yielded one of the most successful brownfields restoration efforts in Florida. It involved a 14-acre (5.7-ha) site of an auto service center that was resurrected into Information Management Resource's (IMR) Global Center headquarters. The project resulted in more than \$51 million in capital investment and was the largest business deal in the city's history. Redevelopment resulted in the construction of six buildings with a total of 310,000 square feet

(28,800 m<sup>2</sup>) of office space. In Bridgeport, Connecticut, a small \$200,000 brownfields grant from the EPA to evaluate polluted property in a prime location was leveraged into more than \$12 million in investments that built a number of structures including a new baseball stadium. In Birmingham, Alabama, a \$200,000 grant was used to address a polluted and abandoned industrial area that was transformed into 2 million square feet (185,800 m<sup>2</sup>) of commercial and industrial space that brought more than 2,000 jobs to the area.

There are numerous other success stories from all around the United States. Although it is a stopgap program, brownfields has resulted in a significant amount of environmental remediation that would not otherwise have been accomplished.

**Bunker Hill Complex Shoshone County, Idaho (1975–1983) Soil Pollution** The Bunker Hill Mine Superfund Site (also called Bunker Hill Company or Bunker Hill Mining & Metallurgical) is in Shoshone County in the panhandle region of northern Idaho, approximately 40 miles (64.4 km) east of the city of Coeur d'Alene between Washington and Montana. Placed on the National Priorities List (NPL) as a Superfund site by the U.S. Environmental Protection Agency (EPA) in 1983, the 21-square-mile (54.4-km<sup>2</sup>) property is contaminated by the residues of lead mining and smelting operations that began in the late 1880s and is one of the largest Superfund sites in the United States.

### BACKGROUND ON THE MINES

The first mines in Shoshone County opened in 1889, extracting lead and silver ores from mineralized veins in Precambrian metamorphosed quartzite and argillite. As geologists and prospectors found more high-grade ore, mining operations expanded, and, in 1917, a lead smelter opened to process and refine ores locally. The population of the area, now nicknamed "Silver Valley" because of the large number of mines, grew rapidly with most people living in the newly established towns of Kellogg, Smelterville, Wardner, and Pinehurst. At its peak of production, the mine area covered 6,200 acres (2,509 ha), was more than one mile (1.6 km) deep, and had nearly 125 miles (201.2 km) of underground roads, adits (horizontal access tunnels), and shafts.

Several features of the Silver Valley ore deposits made them attractive for large-scale mining activities. The area was sparsely populated, and inexpensive land was readily available for the development of infrastructure and support facilities including processing mills, machine shops, and worker housing. The ore was relatively close to major industrial markets on the West Coast and in the Midwest, and

the coal deposits of Montana and Wyoming that would supply the energy needed for processing the ore were nearby. Also, the South Fork of the Coeur d'Alene River flowed through Silver Valley, emptying into Lake Coeur d'Alene, 40 miles (64.4 km) downstream, providing a dependable water supply for ore processing, local agriculture, and drinking.

The removal of metallic lead from the minerals that make up Bunker Hill ore was a three-step process: 1) The ore was crushed into small pieces, and as much non-ore rock, or gangue, as possible was removed either by hand or by mechanical sorting. 2) The concentrated lead ore then was mixed with a limestone flux or coke and heated to a temperature just below its melting point to allow a chemical bond to form with those materials, a process called sintering. 3) The sintered ore was placed in a vat or kettle and fed into a blast furnace, where the carbon in the flux or coke allowed the ore to separate as a molten lead bullion (98 percent pure lead) and sink to the bottom of the container. By-products of the process, called slag, rose to the top of the molten mass and were skimmed off as waste material.

Unlike many of today's modern lead smelting operations, the process used at Bunker Hill was energy intensive and produced enormous quantities of hazardous and nonhazardous waste by-products. Consistent with practices at most mines operating at this time, mine tailings were flushed directly into the Coeur d'Alene River and its tributaries. Lead smelter slag was stockpiled on the ground, without regard to environmental impacts of contaminated runoff or blowing dust. The most significant legacy imposed upon the residents of Silver Valley from the 100+ years of mining that took place there was the lead emitted into the atmosphere.

### CONTAMINATION OF THE SITE

During processing, sintering, and melting of the ore, large amounts of lead-bearing dust were emitted. This particulate quickly settled around and in the vicinity of the mill, where it contaminated the soil, washed into surface water, and leached into underlying groundwater. The lead in this airborne dust represented a serious threat to the health of workers and local residents. Few environmental controls were in place, and particulate-laden water, generated by the washing and processing of lead-bearing ores, was piped directly into either the Coeur d'Alene River or its tributaries. Water was pumped from the mine. Slag was strewn around the valley, close to the mills or wherever it was easiest to place.

By the early 1900s, environmental conditions had deteriorated to the point that even the mine operators

Effects of acid rain on the local ecosystem near the Bunker Hill mine and smelter complex, Idaho, 1991 (© Dan Lamont/CORBIS)

thought changes had to be made. A baghouse was constructed, in 1923, to capture particulate emissions from the smelter. Fumes and dust from lead refining passed through a series of cloth traps, where some of them would be captured. This was only partially effective, and large quantities of lead-bearing particulate still were released from the smelter for another 50 years. In 1938, a central impoundment basin (tailings pond) was constructed on the eastern edge of the Coeur d'Alene River's outwash plain, north of the Bunker Hill Complex. Constructed of low-grade ore and waste rock, the 70-foot- (21.3-m-) high walls of the basin were designed to receive and hold process and mine water, allowing particulate matter to settle out prior to discharge to the Coeur d'Alene River. Like the baghouse, the tailings pond was only partly successful in controlling releases of lead wastes from the Bunker Hill Complex.

Throughout the 1940s and 1950s, mining and processing at the Bunker Hill Complex rapidly expanded, with both workers and residents hesitant to complain about deteriorating environmental quality. Mining provided secure, high-paying jobs, and the economic health of the community depended on the ability of the mining companies in Silver Valley

to produce lead quickly and cheaply. During the 1970s, Bunker Hill was the second largest smelter in the United States, producing nearly one-fifth of the processed lead in the world and more than 20 percent of the country's lead and zinc. Between 1965 and 1981, the smelter released more than 6 million pounds (2.7 million kg) of lead into the atmosphere. Lead emissions increased sharply in 1973, after a fire destroyed a major portion of the baghouse. Company officials, however, decided to continue to operate, using a patchwork of particulate control measures that did little to control emissions. The reason for the haste was primarily that the price of lead was near an all-time high (\$479 per ton, or \$436 per metric ton).

### PUBLIC HEALTH OUTCRY

As public awareness of the dangers of lead increased, political pressure mounted to investigate the effects of mining on the health of those working and living near Bunker Hill. From the 1930s through the 1950s, worker's unions made several unsuccessful attempts to change operating conditions at the smelter and in the mine. It was not until the 1970s, with the passage

of the Federal Clean Air Act and Clean Water Act, that significant environmental improvements began to be made. A \$1-million wastewater treatment plant was constructed at the tailings pond to treat effluent being discharged to the Coeur d'Alene River; however, this effort did not address lead leaking into groundwater through the bottom of the unlined pond. By 1975, the baghouse had been modernized and its flue systems cleaned, repaired, and sealed.

The company operating Bunker Hill, however, fought these and other mandated environmental requirements with an aggressive public relations and lobbying campaign. It hired two public relations companies to publicize its efforts at pollution control. The company purchased homes within a half-mile (0.8-km) radius of the smelter, burned them, and brought in fresh topsoil in a futile effort to revegetate the area. While the company was trying to clean up its environmental image, concern about lead poisoning of workers and their families prompted the Idaho Department of Health & Welfare to test levels of lead in air, soil, and vegetation. Results indicated very high concentrations of lead were present in the environment.

Company officials quietly commissioned their own study, and, in an outrageous breach of medical ethics, urine samples from children in the area were collected and tested without informing the parents or obtaining their consent. The company then refused to release test results. Public outcry and the desire to avoid a study by the Federal Centers for Disease Control forced the company to cosponsor and fund the Shoshone Lead Health Project, a medical monitoring program designed to evaluate blood lead levels in local area children. In January 1975, the results were made public, and of the 172 children living closest to the smelter whose blood lead level had been tested, 170 had lead levels above 40 mcg/dL, the level at which hospitalization is recommended. Emergency medical intervention is recommended at blood lead concentrations above 70 mcg/dL, and 45 children had blood lead levels above 80 mcg/dL. In fact, one of the children tested had more than 160 mcg/dL, the highest blood lead level ever recorded in the United States.

### ENVIRONMENTAL ACTION AND CLEANUP

Investigators found that lead emissions entered soil and water as well as air. For years, mine and smelter tailings had been used to sand icy streets in winter and as backfill around new construction. Lead was broadly dispersed through the Coeur d'Alene River basin and was being connected with the deaths of aquatic organisms, native fish, and hundreds

of migratory waterfowl. Despite several last-ditch efforts to keep the environmental situation under control, the final straw for the Bunker Hill industrial complex occurred in June 1980, when the U.S. Court of Appeals upheld the EPA ambient air quality standard for lead (1.5 mcg/m<sup>3</sup>). By 1982, despite having spent more than \$20 million for pollution control, Bunker Hill could not meet this requirement or other, more stringent environmental standards. As a result, the mine and smelter closed, and 2,000 people lost their jobs.

In 1983, the Bunker Hill Industrial Complex was added to the National Priorities List as a Superfund site. The U.S. Environmental Protection Agency, in cooperation with the state of Idaho, started the cleanup of thousands to millions of tons of mill tailings, mine waste rock, unprocessed ore concentrates, and lead-contaminated soil spread over more than 21 square miles (54.4 km<sup>2</sup>). Included with these materials were the physical facilities associated with the mine, the concentrator, lead smelter, electrolytic zinc plant, phosphoric acid and fertilizer plant, cadmium plant, sulfuric acid plant, and a number of mills. A 200-acre (81-ha) unlined tailings pond also needed to be addressed. This pond was releasing, on average, about 700 pounds (317.5 kg) per day of lead and other metals into the groundwater.

Early cleanup actions included the removal of lead-contaminated soil from 16 public areas (parks, playgrounds), as well as from about 2,000 private and commercial properties. The mine operator filed for bankruptcy in 1994, and tax money had to be used to fund the majority of these efforts. Contaminated materials have been taken back to the site and buried in a specially designed containment area. The major industrial buildings also have been demolished and disposed of in the containment area. A 32-acre (13-ha) mine waste and demolition debris landfill at the former lead smelter was closed and capped, and more than 1.25 million cubic yards (1 million m<sup>3</sup>) of contaminated soil was secured and disposed of on-site. The South Fork of the Coeur d'Alene River was temporarily rerouted so that 30,000 cubic yards (22,937 m<sup>3</sup>) of contaminated sediment could be removed. A three-year outwash revegetation program was initiated to reduce levels of windblown (lead-contaminated) dust.

Although much remains to be done, there are signs that the local environment is beginning to improve. Blood lead levels in children have dropped significantly, to an average of 6 mcg/dL (less than 10 mcg/dL is considered a safe blood lead level), and significant numbers of trout have returned to the South Fork of the Coeur d'Alene River. Bunker Hill remains one of the worst examples of lead poisoning

and environmental contamination in the world. It took almost 50 years for local residents and government officials to recognize the dangers associated with the lack of acceptable pollution control practices in effect at the mine and smelter. The problems were finally recognized and are being addressed.

**Burmah Agate oil spill Houston, Texas November 1, 1979 Water Pollution** By the late 1890s, it had become apparent that the fuel powering the world's economies was shifting from coal to liquid petroleum. David Sime Cargill, an enterprising young Scotsman and already a well-established businessman with warehouses and shipping interests in Ceylon (now Sri Lanka), recognized this trend and founded the Burmah Oil Company (BOC) to gain an early foothold in this new industry. Teaming with another upstart oil company, British Petroleum (BP), Cargill focused his oil exploration, development, and marketing activities primarily within the Indian subcontinent including India, Bangladesh, Bhutan, Pakistan, Nepal, Afghanistan, and Myanmar. The Burmah Oil Company also helped discover and develop major oil fields throughout the Middle East.

As the company grew, it became a more dominant factor within this region's petroleum market. In 1965, BOC was a party to a major constitutional lawsuit in the United Kingdom. During World War II, British army saboteurs blew up BOC-owned oil fields and plantations in Burma (now Myanmar)

to prevent their use by the Japanese. BOC sued for compensation, claiming that the government had, in effect, requisitioned its property and that BOC was due restitution. The House of Lords ruled in favor of BOC, but Parliament quickly passed the War Damages Act of 1965, which indemnified the government from these types of claims. This decision maintained the undue financial burden on the company.

By the early 1970s, BOC was having financial difficulties, and the company was restructured. One of the core businesses it sought to continue was the overseas shipment of crude oil. In 1974, BOC's 772-foot- (238-m-) long merchantman tanker M/T *Burmah Agate* was regularly picking up or delivering up to 400,000 barrels (about 17 million gallons [64.4 million L]) of crude oil to destinations around the world. Registered in Liberia and manned by a mostly Taiwanese crew of 35, the *Burmah Agate* was a frequent visitor to ports in the United States, Europe, and Asia.

#### THE ACCIDENT AND OIL SPILL

On what would become its last voyage, early in the morning of November 1, 1979, the *Burmah Agate* was inbound to the Houston ship channel, making its way toward one of the numerous refineries and terminals that dot this stretch of inland waterway. The Houston-Galveston Ship Channel is the busiest commercial waterway in the United States, with more than 50 ships and more than 300 barge movements taking place on a daily basis. The 50-mile- (80.5-km-) long channel first opened in the late 1800s to break Galveston's stranglehold on commerce into and out of Texas. Today, it is 45 feet (13.7 m) deep and 530 feet (161.5 m) wide. Islands in the ship channel are constructed from dredge spoils and have been designed to serve as bird sanctuaries and wildlife habitat.

The *Burmah Agate* was carrying a full cargo of blended oil with heavier Nigerian crude. Crude oils are often blended or mixed in the pipeline or during loading to improve their handling characteristics and to increase sale price. Heavy crude oils, those that are particularly viscous or thick, such as bitumen, are not readily pumpable at typical surface temperatures and pressures. To help get them physically through the pipeline or refinery, they are sometimes mixed with lighter-weight, more expensive oils. This decreases their viscosity and eases handling. Blended oils also command a higher price than the thicker, lower-grade crude oils because blending also reduces other undesirable features such as acidity or sulfur content. The objective of the blend's “recipe” is to make sure the value of a batch of blended oil

The oil tanker *Burmah Agate* on fire at Galveston Harbor entrance, Texas, on November 1, 1979 (Office of Response and Restoration, National Ocean Service, NOAA)

is greater than the sum of the value of the original crude stock and the value of lighter-weight oils used in the mixing process.

When the *Burmah Agate* was at anchor about five miles (8 km) off the Texas coast, waiting for clearance to enter the ship channel and still well outside the then-three-mile (4.8 km) territorial limit of the United States, with clear skies but rough seas (eight-foot [2.4-m] swells) and in a well-marked shipping channel, it was struck by another Taiwanese-owned ship, the 482-foot- (146.9-m-) long freighter *Mimosa*. The *Mimosa* had just dropped off a load of Japanese steel and was cruising back toward the open waters of the Gulf of Mexico. The collision tore an eight-foot- (2.4-m-) high by 15-foot- (4.6-m-) long hole in the single hull of the *Burmah Agate*, and oil began to pour from the ruptured storage tanks. The *Burmah Agate* immediately burst into flames, and 32 of its crew died almost instantly. Most of the bodies were not immediately recovered, either incinerated at the time of impact or blown overboard. They washed up on Galveston beaches or were found in fishing nets for many weeks after the accident.

The *Mimosa* also caught fire and U.S. Coast Guard helicopters, flying numerous sorties through the smoke and flames, airlifted the crew to safety. The *Mimosa* was a freighter and only carried the fuel it needed to operate but still presented a serious threat. The fire had prevented the crew from shutting off the engines, and the ship, with the starboard anchor set and dragging along the sandy bottom of the gulf, sailed unmanned and out of control in a widening spiral toward a series of submerged capped natural gas wells. The U.S. Coast Guard's on-scene commander, in a daring move, ordered a nearby tug to deploy a thick plastic towrope directly in front of the *Mimosa*. As it sailed over the towrope, the propeller, or screw, became entangled and jammed, and the *Mimosa* was rendered a floating derelict. The deck fires eventually were extinguished, and the *Mimosa* was towed back to Galveston for repairs. If the towrope had not been successful in disabling the *Mimosa*, the U.S. Coast Guard on-scene commander later said, he had been prepared to ram the ship with his own to stop the *Mimosa's* out-of-control progress toward the capped natural gas wells.

Meanwhile, the *Burmah Agate* continued to burn and leak oil. With *Burmah Agate* dead in the water, and with only five of the crew accounted for and most of them critically injured, the owners of the ship quickly assumed responsibility for the cleanup and containment of the oil. They retained a company to fight the fire while another was contracted to minimize the spread of the leaking oil. The oil burned as it cascaded from the *Burmah Agate* and quickly formed a slick about 200 yards (183 m) wide and nearly 1 mile (1.6 km) long. Prevailing winds at this time of year were out toward the open waters of the Gulf of Mexico and helped prevent an immediate ecological catastrophe. Booms and skimmers were deployed to contain the oil within the immediate vicinity of the wreck, and thousands of gallons of foam were sprayed onto the ship to attempt to control the fire.

Firefighting boats created a water curtain, cooling the decks and hull of the *Burmah Agate* that were not ablaze. This allowed a ship to get close enough to pour foam into one of the *Burmah Agate*'s flaming cargo bays. The foam extinguished the fire, but a thunderous explosion tore the ship in half when hot embers ignited explosive vapors that had been given off by the near-boiling oil. At this point, the U.S. Coast Guard declared any attempt to fight the fire too dangerous and decided to let the *Burmah Agate* burn itself out. It took eight weeks, until just after the New Year, for the fires to subside. On January 8, 1980, the fire was declared out and the oil remaining in the bays was lightered (transferred) to another tanker. The *Burmah Agate* was towed to Brownsville, Texas, where, a few weeks later, it was cut up for scrap.

### THE CLEANUP

As the fire burned, the oil still leaked from the tanker, and, by the middle of November, the resulting oil slick had grown to more than 12 miles (19.3 km). By early December, the slick was almost 20 miles (32.2 km) long. A few days after the collision, the prevailing winds changed direction and speed, and, as a result, oil overtopped the containment booms and was washed ashore at Galveston Island, San Jose Island, and Padre Island. Stiff ocean currents, associated with winter weather patterns in the gulf, also forced the oil underneath many of the booms. The oil slick from the *Burmah Agate* fouled approximately 120 miles (193.1 km) of beach.

Cleanup operations included the use of backhoes to scrape contaminated sand into trucks for disposal. This method, however, was found to be

too destructive, and special vacuum trucks were used to suck oil, tar balls, and contaminated sand from the beaches. Some 400 paid professionals and volunteers participated in beach cleanup efforts. As shoreline operations continued, oil containment activities around the *Burmah Agate* were made less effective as the booms regularly caught fire and had to be replaced; some 4,000 feet (1,219 m) of boom burned during the cleanup effort. Special skimmers taken in to back up the booms were sometimes ineffective, often becoming entangled in the booms or being damaged by other recovery vessels or ship channel traffic. A late November storm also shut down both sea and land oil containment efforts for almost a week. Despite these problems, cleanup efforts were declared complete on November 27, 1979. Beach cleanup, oil containment, and firefighting were estimated to cost approximately \$200,000 per day over the response effort. This did not include the value of the cargo or the replacement/repair costs for both ships.

### THE AFTERMATH

Later studies estimated that almost 48 percent of the oil onboard the *Burmah Agate* (about 200,000 barrels, or 31.8 million L) was consumed by the fire. Another 38 percent (about 160,000 barrels, or 25.4 million L) was saved and pumped off the ship into salvage vessels. The booms and skimmers contained slightly less than 2 percent and the remainder was either dispersed at sea (12 percent or approximately 50,000 barrels, or 7.9 million L) or washed up on various Texas beaches, estimated at less than 1 percent, or about 2,100 barrels (33,400 L).

The oil that made its way onshore from the *Burmah Agate* had no significant direct or indirect economic impacts on the local commercial fishing industry. Despite the spectacular nature of the event, the decision by the U.S. Coast Guard to let the oil burn, coupled with aggressive containment of the slick, greatly aided in protecting marine ecology.

An economic impact analysis conducted on the effects of the spill found that there was only a modest decline in tourism along the Texas coast that year, and it was most noticeable in the South Padre Island area. The Burmah Oil Company filed a \$10-million lawsuit against the owners of the *Mimosa* (Juniper Shipping), claiming it was the *Mimosa*'s navigational error that had caused the spill. Later, as the Burmah Oil Company started to expand in the 1990s, acquiring well-known U.S.-based Castrol Oil, it soon ran into financial trouble. In 2000, its long-term partner BP acquired

Burmah-Castrol, as BOC had renamed itself. The bodies of 15 of the *Burmah Agate* crewmen were never found.

**cadmium** Cadmium is a naturally occurring metallic element in rocks and minerals that is most commonly associated with zinc minerals but may also be found with copper and lead, among others. Most cadmium occurs as a minor substitution for zinc in minerals because it has similar properties, but it usually makes up less than 1 percent of the mineral. On the whole, the ratio of zinc to cadmium in zinc deposits is about 400 to 1. Some phosphate ores also contain cadmium in the parts per million (ppm) range, and it can wind up in fertilizers as a result. Cadmium-based minerals are rare and of very minor importance. Of the 25,000–30,000 tons (22,727–27,272 metric tons) of cadmium that are released into the environment per year, half is from the natural weathering of rocks. Most of the rest is from volcanic eruptions and forest fires, and between 4,000 and 13,000 tons (3,636 and 11,818 metric tons) from anthropogenic sources. It is very fortunate that cadmium is relatively rare in the natural environment because it has virtually no benefits, interfering with the absorption of other necessary nutrients such as zinc in most organisms. It occurs in significant quantities in at least 776 of the first 1,467 hazardous waste sites on the U.S. Environmental Protection Agency (EPA) National Priorities List (NPL), making it an important contaminant of concern in the United States. It is ranked the seventh worst environmental pollutant of the 275 listed on the 2007 CERCLA Priority List of Hazardous Substances as a result of this widespread distribution and adverse health effects from exposure.

### PRODUCTION AND USE

Cadmium is an inorganic heavy metal that occurs naturally in rocks, minerals, soils, and volcanic eruptions. It is also used in several industrial processes in many general-use applications and as an important metal in military applications. Cadmium was not discovered until 1817 because it generally occurs so intimately with other metals and in such small quantities that it was difficult to isolate. It is typically a zinc refinery by-product, most commonly in China, Japan, and Korea but also in Mexico, the United States, India, Great Britain, the Netherlands, Peru, and Germany. U.S. production of cadmium declined from 3,150 tons (2,860 metric tons) in 2002 to 1,000 tons (892 metric tons) in 2006, while imports increased from 300 tons (274 metric tons) to 630 tons (574 metric tons) over the same period. The largest producing mines in the United States are the Red Dog Mine, Alaska, and the Pend Orielle Mine, Washington. The current most desirable use of cadmium is in nickel-cadmium batteries, which are rechargeable. They are commonly used in cell phones, cameras, and portable computers, among other products, but are slowly being replaced by lithium-ion and nickel-metal hydride batteries, which are environmentally friendlier. Cadmium has also been historically used in paint pigment, in metal alloys, in both black and white and color televisions, and as a stabilizing compound in plastics. Cadmium is very effective at absorbing neutrons. Consequently, it is used in nuclear reactor control rods, which dampen nuclear chain reactions, thereby keeping the fission process under control. The largest consumer

of cadmium is China, which uses it for batteries, but the worldwide demand for cadmium is slowly decreasing in response to environmental concerns.

### ENVIRONMENTAL RELEASE AND FATE

Cadmium enters the environment through several pathways, primarily through zinc, copper, and lead smelting, and in industrial inorganic chemicals, electroplating, steelworks, and inorganic pigments, in decreasing order of importance. Many of these sources are very localized (point source pollutants) and do not affect many people. The cadmium with the greatest impact on human health is that from nonpoint sources: phosphate fertilizers (41 percent), fossil fuel combustion (22 percent), iron and steel production (17 percent), natural sources (8 percent), nonferrous metals (6 percent), cement plants (2.5 percent), cadmium products (2.5 percent), and incineration (1 percent). Cadmium can enter the atmosphere from industrial plant emissions, volcanic eruptions, and burning. It is generally not a threat, except in the vicinity of cadmium industry, and most settles rapidly to the soil and water systems. In water, much of the cadmium is quickly adsorbed by particulate matter and settles into the sediment, where it can accumulate to significant amounts and pose a health threat in dredge spoils. It can be transported up to 31.3 miles (50 km) from its source, and cadmium-tainted surface water can contaminate soil in some cases. Cadmium tends to be relatively immobile in soils, attaching itself to clay and organic particles. Only a certain rare chemistry of infiltrating water can move it to the groundwater system. The states most affected by industrial cadmium releases to the environment are, in order, Arizona, Utah, Montana, Tennessee, Idaho, Missouri, and Wisconsin.

Human intake of cadmium is most commonly through foodstuffs. Recent estimates are that 95 percent of ingested cadmium is from food, of which 98 percent is from terrestrial food sources through absorption from the soil by plants and continuation up the food chain, with the remaining 1 percent from drinking water and 1 percent from aquatic foods. Cadmium bioaccumulates in the food chain. These numbers change dramatically for tobacco smokers, 50 percent of whose intake is from inhaled smoke, thereby doubling their cadmium exposure. Cadmium intake through foods has decreased steadily since the 1970s in the general public. Cadmium can be greatly concentrated at hazardous waste sites. Whereas it is typically one part per billion (ppb) in water and 250 ppb in soil, near polluted sites, it can be six parts per million (ppm) in water and 4 ppm in soil, a 16-fold increase.

### HEALTH EFFECTS FROM EXPOSURE

Breathing high levels of cadmium in air severely damages the lungs and may lead to death. Ingesting high levels of cadmium causes stomach irritation leading to vomiting, diarrhea, intestinal damage, and possible death. Long-term chronic exposure to cadmium leads to buildup in the kidneys and consequent damage as well as weakened bones. Tests on animals indicate that long-term exposure can cause liver disease, high blood pressure, brain damage, and damage to the immune system. Some animals developed lung cancer from breathing cadmium, but many did not, leaving the carcinogen status questionable. Nonetheless, the EPA, Department of Health and Human Services, and International Agency for Research on Cancer list cadmium as a suspected or probable human carcinogen. Cadmium exposure also decreased birth rate and increased birth defects in laboratory animals, and young animals experience behavioral and learning problems as well as skeletal malformations.

### REGULATION ON HUMAN EXPOSURE

Federal agencies limit human exposure to cadmium because of these adverse health effects. The EPA sets a drinking water limit at 5 ppb under the Safe Drinking Water Act, and the U.S. Food and Drug Administration (FDA) sets a limit of cadmium in dye at 15 ppm. People who work in industries that specialize in cadmium products have a much higher dosage. The Occupational Safety and Health Administration (OSHA) limits worker exposure to cadmium at 5 micrograms per cubic meter of air for an eight-hour-day, 40-hour workweek.

**carbofuran** On July 31, 1998, an entire crew of 34 farm workers in California had to be evaluated and most hospitalized as a result of working in a field that had been sprayed with a mixture of 0.26 percent carbofuran many hours earlier. Incidents like this are not uncommon with exposure to this powerful pesticide. It is the third most toxic field crop pesticide to humans; a quarter teaspoon can be fatal. It is even more dangerous to birds and has been the cause of bird kills throughout the country, killing millions per year. It was for these reasons that carbofuran was designated a Restricted Use Pesticide (RUP) by the U.S. Environmental Protection Agency (EPA) in 1991. Specifically, the granular form looks like seeds to birds and they feed on it. A single granule can kill a small bird, and scavenger birds can be hurt by eating the dead birds. The granular form was banned from all uses for this reason. Carbofuran is also known as Niagara 10242, Furadan 4F or 3G, Brifur, Crisfuran, Chinufur, Curaterr, Yaltox, Pillarfuran, and Kenofuran. All formulations fall into one of two EPA designations: class I, highly toxic, or class II, moderately toxic. As a result of the ban, carbofuran has dropped to number 368 most dangerous pollutant on the 2007 CERCLA List of Priority Substances.

### PROPERTIES, USE, AND PRODUCTION

Carbofuran is a synthetic organic compound that is a broad-spectrum carbamate, insecticide, acaricide, and nematocide. In pure form, carbofuran is a white to light gray crystalline substance with an odor like that of phenol, but its most common forms are granules and liquid; however, the granules have been banned in the United States since 1994. Before 1991, 80 percent of all carbofuran used was in the granular form. It was first available in the United States in 1969 and used in soil and on plants primarily to control beetles and other large insects, aphids, mites, nematodes, and rootworm.

It has been used for a variety of food and other crops but in decreasing applications every year since the bans began. Crops include alfalfa, rice, corn, cotton, tobacco, small grains, and numerous vegetables, fruits, and trees and shrubs. Traditionally, approximately 5 million pounds (2.3 million kg) is used annually in the United States, about 48 percent of which is applied to corn, though in recent years total use has decreased to about 1 million pounds (454,545 kg) per year. In 1994, the granular form was restricted to a maximum of 2,500 pounds (1,136 kg) per year and only for use on spinach seeds, pine seedlings, cucurbits, and bananas. In 1996, application rates and amounts were restricted on alfalfa, cotton, corn, potatoes, soybeans, sugarcane, and sunflowers. California banned the use on corn and sorghum at that time. In 2006, applications to a group of crops, including corn and sorghum, were cancelled, and a four-year phaseout began for several more, including virtually all of the remaining granular applications.

### ENVIRONMENTAL RELEASE AND FATE

As with most pesticides, virtually all that is produced is released as a nonpoint source pollutant. Only at the manufacturing facilities, as the result of improper disposal, or from spills during transport and storage can it be a point source pollutant, a minor occurrence. It is mainly released directly into the soil, where it is moderately persistent depending upon pH, soil type, and moisture. It is broken down by chemical reactions and microbial activity with minor photodecomposition. Removal half-life in natural conditions ranges from 26 to 110 days. Carbofuran is very mobile in silty and sandy loam and silty clay soils, moderately mobile in silty clay loam soils, and slightly mobile in muck (high organics). This high mobility results in leaching and contamination of groundwater. Carbofuran was detected in groundwater in sandy soils in New York and Wisconsin. A recent study of African-American women in urban areas found that 45 percent of them had detectable levels of carbofuran in their blood, an indication that the problem may be much more prevalent. In surface water, carbofuran does not readily evaporate; nor does it settle into sediment. It primarily degrades by pH-dependent chemical reactions, microbial activity, and photolysis. Laboratory experiments showed removal half-lives of one week at pH of 8.0 (alkaline), 8.2 weeks at pH of 7.0 (neutral), and 690 weeks at pH of 6.0 (acidic).

Carbofuran is highly toxic to birds, bees, fish, and aquatic invertebrates on an acute and subacute basis.

It not only affects animals directly but can also damage offspring. It is also highly toxic to mammals on an acute basis. Plants absorb carbofuran through their roots and distribute it throughout the plant, providing another route for ingestion by humans and wildlife.

### HEALTH EFFECTS FROM EXPOSURE

Carbofuran causes very severe health effects through acute exposure because of its powerful toxicity primarily as a cholinesterase inhibitor, but it causes some potential serious long-term effects, as well. Acute exposure primarily affects the central nervous system and produces sweating, dizziness, headache, salivation, weakness, exhaustion, nausea, vomiting, diarrhea, abdominal cramps, labored breathing, blurred vision, muscle twitching, loss of coordination and balance, increased blood pressure, periodic and continuous convulsions, coma, and death from respiratory failure with increasing dosage. It is difficult to conduct long-term studies on carbofuran because of its toxic effects; exposed populations do not survive for an extended period. Generally, carbofuran appears to affect the central nervous system and has weak effects on the reproductive and immune systems. Reproductive effects include reduced fertility, low birth weight, and increased skeletal deformities in offspring of laboratory animals exposed to low doses. The World Health Organization and all federal agencies consider carbofuran to be noncarcinogenic, but in a recent study, the lung cancer risk for people with long-term exposure appeared to be three times as that for nonexposed people. In two studies an increase in cancer in mice was linked to carbofuran exposure. The case, however, is very weak.

### REGULATIONS ON HUMAN EXPOSURE

As already described, carbofuran has numerous use restrictions, bans, and other limitations placed on it by federal agencies, but its commercial use and application as a pesticide are also regulated for environmental and human exposure. The EPA limits the amount of carbofuran in drinking water to 40 parts per billion (ppb) under the Safe Drinking Water Act and recommends a maximum of 50 ppb for a single-day exposure for children. The Occupational Safety and Health Administration (OSHA) set a permissible exposure limit (PEL) of 0.1 milligram in each cubic meter of work area air for an eight-hour day, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) recommended exposure limit (REL) is the same level as for a 10-hour day.

**carbon dioxide** In 2007, carbon dioxide was declared an air pollutant by the United Nations Intergovernmental Panel on Climate Change (IPCC) and, in 2009, by the U.S. Environmental Protection Agency (EPA). Scientifically, this is an unusual event. Unlike carbon monoxide or other previously designated air pollutants such as lead and ozone, carbon dioxide is necessary for life on Earth. It is inside almost every living organism all of the time; exhaled by all members of the animal kingdom, among others; necessary for photosynthesis, and an essential part of the atmosphere. Without carbon dioxide, the Earth would be in a continual ice age because it traps heat in the atmosphere. This new classification of carbon dioxide as a pollutant applies only to the carbon dioxide produced by human activity and is intended to be a measure of global warming. Separating natural from anthropogenic carbon dioxide in air, however, requires advanced analytical equipment that can separate carbon isotopes, because all carbon dioxide has the same basic properties and is completely mixed in the atmosphere. Reducing total carbon dioxide in the atmosphere, therefore, necessarily involves addressing both natural and anthropogenic sources.

**Block diagram showing the carbon cycle and carbon sinks and sources. The main cycle is the exchange of carbon dioxide with oxygen through respiration and photosynthesis. The other main exchange is between the ocean and atmosphere. Rocks and soils act as sinks, and volcanoes and weathering act as additional inputs.**

Carbon dioxide will soon be regulated under the Clean Air Act and will likely be regulated as a pollutant under federal air quality statutes. According to global measurements made in 2004, carbon dioxide is present in the Earth's atmosphere at a concentration of about 380 ppm. In 1750, at the beginning of the Industrial Revolution, CO<sub>2</sub> levels were estimated (from analysis of ice core samples collected in the Antarctic) to be around 275 ppm. There has, therefore, been a 30 percent increase in more than 250 years, most of it since 1945. This increase is almost completely the result of human activity.

### THE CARBON CYCLE

Under ideal conditions, carbon forms a complex cycling in the environment. In the early atmosphere of the Earth, there was no free oxygen but an abundance of carbon dioxide. The development of photosynthetic bacteria called stromatolites resulted in a change in the chemistry of the atmosphere to include free oxygen. In response, animals evolved to utilize stored energy more efficiently by oxidizing it within their cells. This adaptation of cells from prokaryotic to eukaryotic was the single greatest change in the evolution of life. This began a relationship between producers (mostly plants) and consumers (mostly animals) of oxygen. The basic carbon cycle, therefore, involves the removal

of carbon dioxide from the atmosphere by photosynthetic plants and bacteria to produce oxygen and sugars and the consumption of the sugars and oxygen by animals and bacteria to produce carbon dioxide and water.

Over the years, the producers have been far more effective than the consumers because the atmosphere became as oxygen-rich as chemically possible. Much of the sugars and other stored energy was not consumed but was stored underground in hydrocarbons such as coal and oil. There are orders of magnitude more carbon stored in rocks than in accessible hydrocarbons. Another complicating factor is that the oceans act as a sink for carbon dioxide. They not only contain it in the waters, but also sequester it in deposits called carbonates, primarily limestone.

Humans have increasingly disrupted this cycle. In the clearing of forests to grow crops, large producers of oxygen are replaced by much smaller plants, which do not produce as much oxygen. The filling in and destruction of wetlands, which are very effective in capturing carbon and keeping it out of the air (sequestering agents), significantly slow the removal of carbon dioxide from the atmosphere. The burning of wood and other vegetation converts oxygen to carbon dioxide and prevents sequestration. Production of cement and other industrial chemical processes also consume oxygen and return carbon dioxide to the atmosphere. Pollution of the oceans

with toxic chemicals can poison the marine plants and photosynthetic bacteria, thus potentially further disrupting the removal of carbon dioxide from the atmosphere. Oxidation of metals and other anthropogenic materials at the surface also removes oxygen from the atmosphere.

### NATURAL SOURCES OF CARBON DIOXIDE

Even though carbon dioxide emissions from human sources are currently under public scrutiny, there are even more natural sources. The majority of these natural sources are balanced by the natural sinks of carbon dioxide and are primary components of the carbon cycle.

#### Volcanic Eruptions

The lighter elements of oxygen and carbon, dissolved in the molten rock, are expelled, or out-gassed, during the release of pressure and thermal cooling that occurs during and after a volcanic eruption. It was this type of process that helped form the Earth's early atmosphere. Measurements of ongoing volcanic activity indicate that volcanoes discharge about 145 million–255 million tons (132 million–231 million metric tons) of carbon dioxide annually, which is about 1 percent of the amount released by human activities.

#### Decomposition of Once-Living Organisms

As bacteria break down organic tissue, they consume oxygen, and carbon dioxide is given off as a waste product of cellular respiration. This process is continuous and occurs in all but the most extreme conditions in air and water and on land all over the planet. It even occurs in soils beneath the surface of the Earth. One popular idea to solve the carbon dioxide crisis is to sequester it in living organisms. However, unless the remains of the organisms are protected from this process, it will not work.

#### Respiration

When humans exhale, 0.1 gallon (0.5 L) of air is forced from their lungs. The air they breathe in usually contains 79 percent nitrogen, 21 percent oxygen, about 0.04 percent carbon dioxide, along with traces of other gases (argon and helium, among others) and water vapor. Exhaled air is made up of 79 percent nitrogen, about 16 percent oxygen, about 4 percent carbon dioxide, as well as traces of the other gases and water vapor. The most significant change during breathing is the exchange of about 4 percent oxygen for about 4 percent carbon dioxide. This carbon dioxide is a waste gas generated as oxygen is used to break down sugars and fats for energy.

### Evaporation of Seawater from the Ocean

Enormous amounts of carbon dioxide are stored in the Earth's oceans, with some estimates as high as 93 percent of all the free carbon present on the planet. This occurs as the  $\text{CO}_2$  in the atmosphere diffuses into the ocean and reacts with seawater to form carbonic acid and its related bicarbonate and carbonate by-product ions:

Over geologic time, this diffusion of atmospheric  $\text{CO}_2$  into seawater has resulted in the formation of the limestone, dolomite, and other carbonate rocks present in the crust of the Earth. As described in the carbon cycle, the atmospheric-oceanic  $\text{CO}_2$  diffusion process tends to buffer or stabilize the amount of carbon in the air. Since the reactions are reversible, when atmospheric carbon concentrations decline, higher amounts of  $\text{CO}_2$  are released from the ocean. If atmospheric  $\text{CO}_2$  concentrations increase,  $\text{CO}_2$  will tend to diffuse at a higher rate into ocean water. This process can take hundreds of years, however, as most seawater near the surface quickly becomes saturated with  $\text{CO}_2$  and needs to be mixed with deeper waters before absorbing additional  $\text{CO}_2$ .

### THE GREENHOUSE EFFECT

Even though carbon dioxide in the atmosphere occurs in concentrations less than those of many trace gases (e.g., argon is about 9,000 ppm), it is critically important to our survival, because, unlike argon, neon, and other trace gases, carbon dioxide is not inert and plays a vital role in maintaining the climate of the planet.  $\text{CO}_2$  absorbs infrared radiation, trapping the heat of the Sun in the atmosphere and raising the overall temperature of the Earth very gradually over a long period. This is called the greenhouse effect, and it has been found to occur on other planets in our solar system including Venus, Mars, and even Saturn's largest moon, Titan. Other greenhouse gases present in our atmosphere include water vapor, nitrous oxide, and methane. Other than water vapor, carbon dioxide is by far the most plentiful.

The term *greenhouse effect* was coined by a French mathematician and physicist named Jean-

Baptiste-Joseph Fourier. Born in 1768, he was the son of a tailor; at the age of 16, he became an instructor of mathematics at a prestigious military school in Auxere, France. Although he had an interesting history with his relationship with Napoléon Bonaparte, his most famous work was as chair of analysis at the Ecole Polytechnique in Paris. Fourier is best known for his work demonstrating how the conduction of heat in solid bodies can be analyzed in terms of infinite mathematical sequences, now called Fourier series. The equations developed by Fourier allowed enormous breakthroughs in the fields of heat flow and acoustics. One of his most important works was published in 1822 and entitled *The Analytic Theory of Heat*. In it he describes *l'effet de serre* (literally, “glasshouse effect”), today called the greenhouse effect.

In a steady-state system, as temperatures rise because of increased CO<sub>2</sub> in the atmosphere, additional plant growth will occur and CO<sub>2</sub> will be removed at increased rates for use in photosynthesis. Also, diffusion of carbon dioxide into the ocean will increase, and this too will act to remove excess CO<sub>2</sub> from the atmosphere. As CO<sub>2</sub> is removed, temperatures fall, plant activity slows, and diffusion of CO<sub>2</sub> from the oceans into the atmosphere increases. This would allow carbon dioxide levels to increase gradually and global temperatures to begin, once again, to rise. Eventually, a balance would be reached.

Many scientists believe that human activities, most importantly the burning of fossil fuels, coupled with developmentally driven deforestation, especially in the rain forests of Central and South America, may be overwhelming these naturally occurring carbon dioxide control mechanisms. The combination of increased CO<sub>2</sub> emissions from fossil fuel usage and reduction of plant growth could allow CO<sub>2</sub> levels to increase to catastrophic levels. This scenario is documented by the increase in CO<sub>2</sub> levels, and, since 1950 alone, the average surface temperature of the Earth has increased by 0.7°F, or 0.4°C. There is still some, albeit decreasing, controversy regarding the extent of the enhanced, or anthropogenic, greenhouse effect.

Opponents of the enhanced greenhouse effect idea maintain that the Earth has been warming since the last glacial maximum some 18,000 years ago and that there is a periodicity, or natural cycle, of long-term global heating and cooling. In addition, while accumulation of carbon dioxide may be a contributing factor to global warming, the real mechanisms are nonanthropogenic, including increased cosmic ray activity, variations in volcanic activity, variations in intensity of solar radiation, distance between Earth and Sun, or other causes. Credible scientific data supporting an enhanced greenhouse

effect are starting to become difficult to reconcile with these opinions. In 1995, the United Nations Intergovernmental Panel on Climate Change (IPCC) stated, “The balance of evidence suggests a discernible human influence on global climate.” In 2001, the IPCC issued a second, even more definitive statement: “There is new and stronger evidence that most of the warming observed over the last 50 years is attributable to human activities.”

Supporting this finding was an independent report published later that same year by the U.S. National Academy of Sciences (NAS). The NAS reached a similar conclusion but also indicated that natural sources are a likely contributor to the problem:

Greenhouse gases are accumulating in Earth's atmosphere as a result of human activities, causing surface air temperatures and subsurface ocean temperatures to rise. Temperatures are, in fact, rising. The changes observed over the last several decades are likely mostly due to human activities, but we cannot rule out that some significant part of these changes are also a reflection of natural variability.

As the temperature of the Earth rises, significant changes to global climate are likely to occur. And, since much of human activity is dependent on climate, these changes can result in major disruptions to the worldwide economy, agriculture, and sustainability of our communities.

## IMPACTS OF THE GREENHOUSE EFFECT

### Agriculture

Impacts of global warming on agriculture have been hotly debated, with some researchers stating that a warmer climate will provide an overall beneficial effect, while others make the case for a farming catastrophe. Agriculture in the northern United States and Canada could benefit from warmer temperatures, while agriculture in the southern United States could be harmed as summer temperatures rise and increase the need for additional irrigation. In countries with less developed and more fragile agricultural systems, the effects could be ruinous, as increased rainfall and longer growing seasons will require more active pest management and produce less predictable farming conditions.

### Coastal Resources

Some global warming models predict major rises in sea level as winters become milder and ice sheets melt. If a 20-inch (50-cm) rise in ocean waters were to occur—as, according to some predictive scenarios is possible by the year 2100—more than 5,000

square miles (12,950 km<sup>2</sup>) of coastal land in the world would be submerged. A rising sea level would force major evacuations of densely populated coastlines or extensive public works projects to hold back the rising water, not only in the United States, but also in other countries around the world. There also is evidence that the intensity of major storms may increase with increasing temperature, causing severe coastal damage.

### Energy and Transportation

Warmer temperatures will require additional energy for cooling in some areas and decrease energy usage for heating in others. Although winter transportation may become easier, increased flooding or lower water levels may negatively affect transportation of goods and people by water in some areas, while enhancing it in other areas. Removal of the ice in the Arctic Ocean will certainly improve ship traffic.

### Human Health

The direct effects of global warming on human health are mainly subtle and long-term. Mortality from long-term heat stress and related diseases, especially among the young, elderly, and sick, will probably increase. As precipitation and temperature patterns change, new breeding sites for insects and other pests will develop. There may be a shift in the range and occurrence of infectious diseases, as well. Increased intensity of tropical storms, shifts in food-producing areas and their outputs, availability of freshwater, and other direct effects of global climate change also will affect human health.

### Water

Changes in precipitation patterns, with rainfall increasing in some areas, decreasing in others, would affect the quality and quantity of available drinking water. Also affected would be the availability of water used for irrigation, cooling, electrical generation, and other industrial applications. Increased evaporation may change local water chemistries, increasing salt content with increased rainfall, causing more frequent flooding and erosion.

### Ecology

For global ecosystems, increases in Earth's temperature and the related variations to local climates also have several significant impacts, including affecting the ranges, numbers, metabolisms, and behavior of a variety of plants and animals. Ecological timing or interaction of species plays a key role in the health of an ecosystem. Plants flower, for example, when insects are most available to assist in pollination. If the diverse species of an ecosystem respond to

increasing temperatures in different ways, then the carefully balanced, fragile biology of an ecosystem will be endangered.

The geographic spread or occurrence (ranges) of certain sensitive plants and animals has shifted already in some cases. Many southern and lower-elevation populations have begun to move northward and upward, as they find temperatures warmer and more hospitable. One of the most obvious examples is the range of the North American red fox. As temperatures warm, its range has increased northward to the point where it may soon overwhelm the habitat of its close cousin, the arctic fox. Other instances of range shifts, particularly in the United States, have been well documented for plants, birds, mammals, and intertidal invertebrates. Such shifts can alter vital competitive and predator/prey interactions. This results in a reduction of local or even regional biodiversity.

Ecological impacts of increased carbon dioxide levels, however, cannot be evaluated as a stand-alone issue. There are numerous other stresses currently threatening important habitats and species. Loss of access to undeveloped land due to construction, appearance of invasive species, and impacts related to industrial development, such as soil and water contamination, are likely to cause further stress on species range and diversity as well as associated ecosystems.

## CONTROL OF CO<sub>2</sub> EMISSIONS

Unlike for many of the other air pollutants, there is no simple solution to the emission of carbon dioxide from the combustion of fossil fuels. Humans are extremely dependent on fossil fuels, and they produce enormous quantities of CO<sub>2</sub> when they burn them. Exhaust gas concentrations of other common pollutants such as SO<sub>x</sub> or NO<sub>x</sub>, which have to be controlled, are in the parts per million range, which is small and more easily managed. As fossil fuels are burned, however, carbon combines with oxygen to form carbon dioxide. Since oxygen adds mass, the carbon dioxide weighs more than the original, unburned fuel. For example, on a unit per unit of energy basis, coal emits the most carbon dioxide when burned, about three pounds (1.36 kg) for every one pound (2.2 kg) of coal used. Liquid petroleum fuel (LPF, gasoline and diesel, for example) emits less CO<sub>2</sub> than coal, but quite a bit, about 2.75 pounds (1.25 kg) of carbon dioxide per pound (2.2 kg) of LPG. Natural gas emits the least of the fossil fuels, about 1.35 pounds (0.6 kg) of CO<sub>2</sub> per pound (2.2 kg) of natural gas. In real terms, this means that each tank of gasoline will release about 400 pounds (181 kg) of carbon dioxide. There are more than 600

million motor vehicles in the world today, and, if present trends continue, the number of cars on Earth will double in the next 30 years.

In 2009, total U.S. greenhouse gas emissions were 6 billion tons (5.4 billion metric tons) of carbon dioxide, which is about 19 percent of the global emission load of 29 billion tons (26 billion metric tons). The primary sources of U.S. anthropogenic greenhouse gas emissions were from the generation of electricity and transportation, which accounted for more than 70 percent of total carbon dioxide releases. The use of coal in the United States to generate electricity accounts for approximately 40 percent of the total anthropogenic carbon dioxide released into the atmosphere on an annual basis, about 2.5 billion tons (2.2 billion metric tons). Transportation-related discharges of carbon dioxide contribute another 32 percent of the total anthropogenic atmospheric load, some 2.1 billion tons (1.9 billion metric tons).

The only practical way to reduce carbon dioxide emissions is to reduce the amount of fossil fuel burned, either through improving burner efficiency (smaller, less powerful cars) or by using an alternate, non-carbon-based fuel (e.g., geothermal, hydrogen, or nuclear). Currently, neither of these approaches has much popular economic or political support in the United States.

Internationally, several countries have joined to try voluntarily to limit the amount of greenhouse gases, mostly carbon dioxide, that they discharge into the atmosphere. The Kyoto Protocol, also called the Kyoto Protocol to the United Nations Framework Convention on Climate Change, is an international agreement on global warming that was negotiated in Kyoto, Japan, in December 1997. More than 150 countries have signed the agreement. The United States signed the protocol, but the Clinton administration did not submit it for ratification to the U.S. Senate because they knew it would be defeated. It is, therefore, nonbinding. Australia, citing concerns relating to potentially severe economic impacts, did not sign it. Those countries signing the agreement are obligated to reduce their emissions of carbon dioxide along with five other greenhouse gases by 5.2 percent, compared to the baseline year of 1990. Country-specific goals vary from 8 percent reductions for the European Union to 7 percent for the United States, 6 percent for Japan, and 0 percent for Russia. Australia and Iceland are allowed increases of 8 percent and 10 percent, respectively. If emission targets are not met, then financial penalties are imposed on the offending country.

If fully implemented, the Kyoto Protocol may reduce the average increase in global temperature by between 0.04°F and 0.5°F (0.02°C and 0.28°C)

by the year 2050. If left unchecked, current global temperatures may rise 2.7–9.8°F (1.4–5.8°C) by that time. Although it is a significant first step, many environmentalists are critical of the agreement, asserting that it is not stringent enough, and that without the participation of the United States and other developing countries (such as China and those in Africa and South America), its value is questionable.

For the United States, agreeing to limit carbon dioxide emissions is a difficult decision, as it may limit future economic growth. It would mean, for example, that power plants may not be able to generate significant amounts of new electricity. It also may force the closing of older, coal-fired generating plants, which produce about half of the nation's electricity. This would increase dependence on natural gas, which is already becoming more difficult to find, and imports of foreign oil. Higher costs to both consumers and business would be the end result.

Although leadership at the federal level for control of carbon dioxide emissions is weak, action is being taken at the local level. In November 2004, nine northeastern states—Maine, Massachusetts, New Hampshire, Vermont, Rhode Island, Connecticut, New York, New Jersey, and Delaware—formed the Regional Greenhouse Gas Initiative. This program is a state-level CO<sub>2</sub> emissions capping and trading organization. Almost 20 large American cities have voluntarily agreed to comply with Kyoto Protocol greenhouse gas emission limits. These types of grassroots commitments may be successful at pressuring the federal government to focus on the need to reduce carbon dioxide emissions.

**carbon monoxide** It is estimated that between 1979 and 1988, there were 56,133 deaths in the United States as the result of carbon monoxide poisoning, classifying it among the most dangerous environmental hazards. Of these deaths, 25,889 are regarded as suicides, making carbon monoxide among the most popular choices for suicide. Some 11,547 deaths were unintentional, 6,552 (57 percent) from motor vehicle exhaust, 83 percent of which were not moving. Poisoning through smoke from house fires was responsible for 15,523 of the deaths. Even today with extensive efforts of education and awareness, unintentional carbon monoxide poisoning still claims up to 500 lives per year and sends between 15,000 and 40,000 people to the hospital per year. Another 2,000 die from suicide. Carbon monoxide is also known as CO (its chemical formula), coal gas, coal fumes, wood gas, mine damp, white damp, and carbon oxide. It is the properties of this extremely common gas and its interaction with blood through respiration that make it so dangerous. Most people across the globe are exposed to carbon monoxide every day, and many are sickened and die as a result. Carbon monoxide is ranked number 189 of the top 275 most dangerous pollutants on the 2007 CERCLA Priority List of Hazardous Substances as a result of this threat to public health.

### PROPERTIES, SOURCES, AND USE

Carbon monoxide is a colorless and odorless toxic gas that is slightly lighter than air. It is also highly flammable. It is the result of incomplete burning of any kind of fuel in an oxygen-poor environment. Exhaust from motor vehicle traffic is the most common source of carbon monoxide, making up 56 percent overall and up to 85–95 percent in urban areas. The second major sources are stationary engines and nonroad vehicles, including construction equipment, airplanes, and boats, which contribute 22 percent of the carbon monoxide budget. Fuel combustion in furnaces, woodstoves, gas stoves, kerosene space heaters, and fireplaces makes up 6 percent. Industrial processes such as metal smelting and processing and chemical manufacturing contribute 4 percent. The remaining 12 percent is from miscellaneous sources, such as tobacco smoke, house fires, forest fires, outdoor grilling, incinerators, and certain

organic chemicals including carbon tetrachloride. It is estimated that annual global emission of carbon monoxide totals 3 billion tons (2.6 billion metric tons), 60 percent from human activities and 40 percent from natural sources.

Carbon monoxide was first mentioned, in the third century B.C.E., in ancient Greece, where coal fumes were said to cause extreme sinus pressure (heavy head), disorientation, and death. The first chemical distillation and isolation of pure carbon monoxide and the first complete description of coal gas poisoning were in 1775–76. The identification of carbon monoxide as the toxic substance in coal gas, however, was not made until 1800. Despite knowledge about its toxicity, carbon monoxide poisoning ran rampant for many years, especially through the use of illuminating gas. In 1927, for example, 611 people died in New York City alone of carbon monoxide poisoning. Edgar Allan Poe is believed by some to have suffered from chronic carbon monoxide poisoning from illuminating gas. One report suggests that haunted house reports may actually have been the result of hallucinations and impact on hearing by chronic carbon monoxide poisoning. Such reports flourished during the 19th and 20th centuries when coal furnaces and illuminating gas resulted, in general, in increased carbon monoxide in indoor air.

Carbon monoxide is also an industrial gas with widespread uses, primarily in chemical manufacturing. It is used in the production of aldehydes, some detergents, methanol, acetic acid, and metal carbonyl complexes. It is also used to treat fresh meat and fish. By combining with hemoglobin and other substances, it prevents oxidation and keeps meats red, an appearance that consumers typically associate with freshness, although not always accurately. Carbon monoxide also has medical applications. Formerly, it was used as a fuel because it is flammable and as a poison for executions.

### ENVIRONMENTAL RELEASE AND FATE

Global background levels of carbon monoxide are between 0.05 and 0.12 part per million (ppm). There was a 1–2 percent increase per year in these levels during the 1980s, but a sharp decline beginning in 1989–92 continues today. In many cities, the average level of carbon monoxide in the air is 17 ppm, with spikes to 53 ppm. Carbon monoxide levels in motor vehicles are typically two to five times as high as in ambient outdoor air. Indoor ice skating rinks can have levels of 148–354 ppm as the result of exhaust from the resurfacers. Similarly, tunnels can have 65–165 ppm. Other areas of danger are kitch-

ens with gas stoves, household utility rooms with gas dryers and water heaters, and parking garages. The concentrated sources and limited circulation of these areas can drive carbon monoxide levels to more than 100 ppm on a regular basis. Environmental tobacco smoke can increase concentrations 20–40 ppm in rooms for periods of up to eight hours after smoking has ceased.

### HEALTH EFFECTS FROM EXPOSURE

Carbon monoxide is inhaled into the lungs, where it is respired into the bloodstream. It chemically attaches (bonds) to the hemoglobin in place of oxygen. These bonds are much stronger than oxygen bonds (up to 200 times as strong) and produce a compound called carboxyglobin (COHb). This process deprives the organs and muscles of needed oxygen. Exposure to carbon monoxide produces both immediate and slowly developing adverse health effects, some of which do not dissipate quickly. Acute exposure produces several flulike symptoms even at concentrations of 5 percent or less, including headache, dizziness, muscle weakness, fatigue, nausea, vomiting, chest pain, confusion, and, at very high levels (40 percent or more), hallucinations, unconsciousness, coma, and death. Death typically arrives by cardiac arrest and may be preceded by electrocardiographic changes, arrhythmias, and pulmonary edema. Long-term chronic exposure can lead to a serious condition called carbon monoxide poisoning syndrome. Symptoms of this syndrome include all of those from acute exposure, including headache, nausea, vomiting, chronic fatigue, dizziness, hallucinations, and vertigo. Other symptoms depend upon the level of exposure; they include muscle and joint pain, tingling and numbness, muscle weakness, memory loss, inability to concentrate, slowed thinking, apathy, irritability, lack of coordination, depression, anxiety, sleep disturbance, personality changes (psychosis, schizophrenia), vision and hearing problems, eating disorders, hypersensitivity to chemicals, aphasia, and seizures. Several of these symptoms, especially those of a psychological nature, may begin two to 28 days after poisoning has ended and last for long periods or even become permanent depending upon the degree of poisoning and the sensitivity of the individual.

If pregnant women experience carbon monoxide poisoning even at relatively low concentrations, there can be severe damage to the fetus. Typically, there is an increase in stillbirths, spontaneous abortion, premature birth, and early postnatal death. If the baby survives, common effects are low birth weight, brain damage, cleft palate and lip, malformation of the mouth, low-set ears, birth defects in

the legs and arms and external genitalia, a number of heart defects, Down Syndrome features, limited to no reflexes, speech problems, cerebral palsy, seizures, visual and auditory impairment, mental retardation, autism, emotional instability, and anxiety.

Certain groups of people are more susceptible to carbon monoxide poisoning than others and have adverse health reactions at lower doses. These groups include unborn babies, infants, and older people who have chronic heart disease, anemia, or respiratory problems. People who suffer from heart-related diseases including angina, clogged arteries, or congestive heart failure may suffer severe chest pain and profound weakness from a single low-level exposure to carbon monoxide. Multiple exposures may cause significant cardiovascular damage. People at high elevations in low-oxygen settings typically react more strongly to carbon monoxide poisoning, as do people who may be environmentally exposed to carbon monoxide, such as cigarette smokers.

### REGULATIONS ON HUMAN EXPOSURE

Many governmental regulatory agencies of the United States and other countries limit exposure of carbon monoxide for workers and the general public. The Occupational Safety and Health Administration (OSHA) has established their permissible exposure limit (PEL) at 50 ppm for an eight-hour-day, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) recommended exposure limit (REL) is 35 ppm for a 10-hour day and a short-term ceiling (STEL) of 200 ppm. They set the immediately dangerous to life and health (IDLH) designation at 1,200 ppm or more. The National Ambient Air Quality Standards for the United States for carbon monoxide in outdoor air are 9 ppm for eight hours and 35 ppm for one hour. The World Health Organization recommends maximal exposures of 90 ppm for 15 minutes, 50 ppm for 30 minutes, 25 ppm for one hour, and 10 ppm for eight hours. Probably the most effective regulations of carbon monoxide exposure are those that require detectors in offices and residences. In many areas, houses may not be given a certificate of occupancy without a working carbon dioxide detector. Air pollution devices that are now required on all automobiles substantially reduce emissions, eliminating up to 99 percent of CO from exhaust gases in new cars. The required gasoline additive methyl tert-butyl ether (MTBE) was found to reduce carbon monoxide by 40 percent.

**carbon tetrachloride** Carbon tetrachloride is a synthesized organic compound with extensive but declining industrial applications. It has been used as a cleanser for machines and electrical equipment, as a solvent for rubber cement, in the production of nylon as well as other chlorination procedures in organic compounds, as a gasoline additive, for etching of aluminum integrated circuit boards, in the manufacture of pharmaceuticals, as an ingredient of insecticides, and in the production of oils, fats, perfumes, soap, lacquers, varnishes, rubber, wax, and resins, among other products. It also forms impact-sensitive explosive mixtures with certain metal particulates and halogen compounds. Previously, it was a major component in dry-cleaning agents and fire extinguishers, but concerns over its effect on public health limited its use. The main reason for the decline in its usage, however, is that it is the primary chemical in the production of chlorofluorocarbon (CFC) propellants and refrigerants. These compounds have been shown to be the major cause of the deterioration of the ozone layer at the North and South Poles, and, as a result, their production and use have been strongly curtailed. As a result of the direct adverse health effects, the effects on stratospheric ozone, and its very wide distribution, carbon tetrachloride was rated the 47th most dangerous pollutant on the 2007 CERCLA Priority List of Hazardous Substances.

**PROPERTIES AND PRODUCTION**

Carbon tetrachloride is a heavy, clear organic liquid with a chloroformlike sweet smell and the ability to evaporate very quickly. It is classified as a volatile organic compound (VOC). It was put into produc-

tion in 1907 and immediately used in numerous chemical applications. Some of the trade names and synonyms of carbon tetrachloride chemicals include perchloromethane, methane tetrachloride, Benzinoform, Univerm, Nectorina, Faciolin, Flukoids, R 10 (refrigerant), Tetraform, Tetrasol, Halon 104, and Freon 10, 11, and 12. Domestic production and importation have varied over the years, with peak U.S. production in 1974. Its use was severely restricted in the mid- to late 1970s because of environmental concerns, but, in 1987, some 672 million pounds (305 million kg) was produced and 111 million pounds (50.5 million kg) imported. Domestic production increased in 1989 to 761 million pounds (346 million kg) but decreased to 315 million pounds (143 million kg) by 1991 and 110 million pounds (50 million kg) by 1997 with no imports by 2000. Use of carbon tetrachloride is anticipated to continue to decrease by 7.9 percent per year as it is phased out.

**ENVIRONMENTAL RELEASE AND FATE**

Carbon tetrachloride occurs in at least 430 of the first 1,662 EPA Superfund sites on the National Priorities List. From 1987 to 1993, nearly 76,000 pounds (34,550 kg) of carbon tetrachloride was released into the environment from industrial sources. In decreasing order, the top five states producing the most carbon tetrachloride were Texas, West Virginia, Louisiana, Alabama, and California, primarily from the chlorine and alkalis industry with far lesser amounts from the inorganic chemicals industry, petroleum refining, organic chemicals industry, and agricultural industry. Carbon tetrachloride is released primarily into the atmosphere from industrial sources. Even if discharged into water or on land, it is so volatile that much evaporates into the atmosphere. It is extremely stable in the troposphere, with a residence time of 30–50 years, and, therefore, even though production has been reduced, the volume will continue to increase for several more years. The primary release of carbon tetrachloride from the troposphere is slowly into the stratosphere, where it photolyzes and dissociates ozone.

Carbon tetrachloride enters the surface water system from such sources as industrial spills, wastewater from metal manufacturing industry, agricultural runoff, washing out of the atmosphere through precipitation, and petroleum refining. It is primarily a point source pollutant. At the surface, it quickly evaporates, and this is by far the major way it is removed from the environment. Some bacterial biodegradation also occurs deeper in the water. Carbon tetrachloride is introduced into soil by industrial spills, agricultural runoff, leaching from landfills,

and dumping. Once in the soil, much carbon tetrachloride simply evaporates, while most of the remaining carbon tetrachloride, being highly mobile, moves quickly into the groundwater system because of its poor adsorption into soil and sediment.

### HEALTH EFFECTS FROM EXPOSURE

There are several adverse health effects from exposure to carbon tetrachloride, which were the primary reason for its initial decrease in production. Acute short-term exposure through inhalation or ingestion affects the central nervous system, producing headache, dizziness, vertigo, depression, confusion, loss of coordination, and, in very high doses, respiratory failure, coma, and possible death. The gastrointestinal tract is also affected; nausea, abdominal pain and cramping, and diarrhea result. After the acute symptoms subside, liver and kidney damage may appear. Typically, inhalation exposure to 1,000 parts per million (ppm) of carbon tetrachloride over a few minutes to an hour will cause narcotic effects in everyone, but people vary greatly in their response. Alcohol greatly increases the effects of carbon tetrachloride to the point where an alcoholic is in jeopardy of losing his or her life after only 15 minutes of a 250-ppm exposure. Long-term chronic exposure to carbon tetrachloride can result in additional adverse health effects. Even doses as low as 10 ppm for extended periods can cause liver and kidney damage, and lung damage has been reported in animals as a secondary effect of the kidney damage. Long-term exposure also causes damage to the eyes, with doses as low as 6.4 ppm for one hour per day for an average of 7.7 years. These effects include reduced sensitivity of the cornea, changes in perception of color, changes in the visual field, and inability to adapt to dark areas. Reproductive effects of exposure to carbon tetrachloride have been found in studies of rats. Mothers and fetuses showed marked effects of toxicity and increased resorption of fetuses, and male rats showed testicular degeneration. Rats also developed liver and related cancers, as did mice and hamsters after long-term exposure. On the basis of the development of cancers in rats, carbon tetrachloride is considered a probable human carcinogen.

### REGULATIONS ON HUMAN EXPOSURE

As a result of these adverse health effects, several federal agencies restrict human exposure to carbon tetrachloride. The U.S. Environmental Protection Agency (EPA) has set a recommended maximal contaminant limit (MCL) of five parts per billion (ppb) of carbon tetrachloride for drinking water. They further require the reporting and investigation of any spill of 10

pounds (4.54 kg) or more. The Occupational Safety and Health Administration (OSHA) set an exposure limit of 10 ppm in work area air for an eight-hour workday, 40-hour workweek. For peak exposure, the limit is 200 ppm for five minutes in any four-hour period. The National Institute of Occupational Safety and Health (NIOSH) recommends a short-term exposure limit (STEL) of 2 ppm for 60 minutes and an immediately dangerous to life and health (IDLH) exposure level of 200 ppm. OSHA estimates that there may have been as many as 3.4 million workers either directly or indirectly exposed to carbon tetrachloride and that up to 8 million people living within 12.5 miles (20 km) of manufacturing facilities may be exposed to unhealthy levels.

**Carson, Rachel (Rachel Louise Carson) (1907–1964)** *American Environmentalist, Biologist* Rachel Carson is considered by most environmentalists to be the mother of the American environmental movement by virtue of her battle against pesticides and dichlorodiphenyltrichloroethane (DDT) in particular. It is truly astounding that in a time when women were struggling to be regarded as serious contributors in many fields, this private, unassuming woman could spearhead such a major movement. Against overwhelming odds and

extraordinary efforts of major chemical companies to suppress her work and discredit her both professionally and personally, Carson managed to capture the interest of the American public and even the top level of government. She testified in Congress on the dangers of pesticides, and after President Kennedy read her book *Silent Spring*, he ordered the investigation of all pesticides that Carson had identified as dangerous. Eventually, this pioneering work would lead to the first bans on dangerous chemicals and the formation of the U.S. Environmental Protection Agency (EPA). Although the battle to save the environment is far from over, the fact that a battle is being waged is largely the result of the vision and sacrifices of Rachel Carson.

### BIOGRAPHICAL INFORMATION

Rachel Carson was born on May 27, 1907, in the small town of Springdale in the Allegheny Valley of Pennsylvania. She grew up on a small farm, where her mother instilled in her a love of nature. Even as a child, Rachel showed a talent for writing, publishing her first work, titled “A Battle in the Clouds,” in the *St. Nicholas Literary Magazine* for children at age 10. In 1925, she entered the Pennsylvania College for Women, which would later become Chatham

Rachel Carson displays her book *Silent Spring* in her library in Silver Spring, Maryland, March 1963. (AP Images)

College. She began as an English major but switched to biology and graduated with a bachelor's degree in 1929 magna cum laude. Carson earned a scholarship to continue her studies at Johns Hopkins University in Baltimore, Maryland, where she graduated with a master's degree in zoology in 1932. Her thesis was titled “The Development of the Pronephros during the Embryonic and Early Larval Life of the Catfish.” The pronephros is a temporary kidney that is formed during the development of permanent kidneys. Upon graduation, she taught zoology at the University of Maryland while continuing her research during the summers at the Woods Hole Oceanographic Institution in Cape Cod, Massachusetts.

In 1935, Rachel Carson accepted a part-time position at the U.S. Bureau of Fisheries, where she wrote science scripts for a radio show called *Romance under the Waters* and supplemented her income by writing articles on natural history for the *Baltimore Sun*. This part-time position led to a full-time position as junior aquatic biologist in 1936, when she became the first woman to take and pass the civil service exam. Over the next 15 years, Carson would rise through the ranks of the successor organization, the U.S. Fish and Wildlife Service, to become the chief editor for all its publications. During this short career, Rachel Carson wrote several books, the income from which allowed her to retire, in 1952, at age 45 to devote herself completely to writing. She bought land on the Sheepscot River near West Southport, Maine, and built a cottage for writing but also kept a residence in Silver Spring, Maryland.

Rachel Carson's life was fraught with personal tragedy. These tragedies began in 1931, when her family was forced to give up its farm, in part, because they were affected financially by the Great Depression but also because two large chemical plants were built on each side of the farm, thus reducing the land's value and its agricultural capacity. Then, in 1935, her father died suddenly, leaving Rachel to care for her mother. In 1936, her sister died, leaving two orphaned children whom Carson and her mother would raise. Her niece became ill in 1959 and eventually died, leaving an orphaned son whom Carson adopted. Her mother died, the same year, and Carson was diagnosed with breast cancer. After a long struggle with the illness, Rachel Carson died on April 14, 1964, at her home in Silver Spring, Maryland, at the young age of 56.

### PUBLICATIONS

Considering the great success of her books, it is surprising that Rachel Carson faced so many hurdles to publication. Her first article in a national maga-

zine, titled “Undersea,” was published in *Atlantic Monthly* in 1937. Her first book, *Under the Sea-Wind*, was published in 1941, but, although receiving good reviews from critics, it was largely unnoticed primarily because America’s attention was focused on the onset of World War II. As her concern over the environment grew, her writings then became more geared toward environmental activism. Her work on the origins and geological aspects of the oceans was rejected by 15 magazines, including *National Geographic Magazine* and the *Saturday Evening Post*. Under the title *A Profile of the Sea*, it was finally published by the *New Yorker* as a serialized collection, although parts of it were also published by *Yale Review*, *Science Digest*, and *Nature*. The entire manuscript was then published in 1951 as the book *The Sea around Us*, which sold more than 200,000 copies in hard cover in its first year. It was on the *New York Times* best-seller list within two weeks and remained there for a record 86 weeks, in 39 of which it was in the top position. It later won the John Burroughs Medal and the 1952 National Book Award and was voted Outstanding Book of the Year in the *New York Times* Christmas Poll. As a result of this mark of distinction, Carson was awarded honorary doctoral degrees from Pennsylvania College for Women and Oberlin College. Her first book, *Under the Sea-Wind*, was rereleased and made the *New York Times* best-seller list. Carson’s next book, *The Edge of the Sea*, was released in 1955 and also made the best-seller list. The National Council of Women of the United States named it Outstanding Book of the Year, and it earned her an achievement award from the American Association of University Women. Carson continued to publish articles during this time including “Help Your Child to Wonder,” published in *Woman’s Home Companion* in 1956 and posthumously released as the book *The Sense of Wonder* in 1965. Her environmental activism culminated in 1957–61, when she wrote her final and most famous book, *Silent Spring*. It was first serialized by the *New Yorker* in June 1962 before being published as a book the same year. It made the top of the best-seller list within two weeks and remained on the list for many years.

### **SOCIAL IMPACT OF HER WORK**

In 1992, *Silent Spring* was named the most influential book of the last 50 years by a congressional panel. More recently, it was designated as one of the 25 greatest science books of all time by the editors of *Discover Magazine*. Indeed, it remains in print to this date. In terms of historical importance and

social impact, it has been compared with Harriet Beecher Stowe’s *Uncle Tom’s Cabin* and Charles Darwin’s *On the Origin of Species*. Although her earlier books created a following for Rachel Carson and fervor of environmentalism, it was *Silent Spring* that elevated her to the leader of the movement. The book identified chlorinated hydrocarbons and organophosphates as the most dangerous pesticide pollutants and named specific compounds to be avoided, especially DDT. It also coined the term *ecosystem*, which became an important concept in environmental studies.

If the period 1957–64 had been carefully orchestrated to set the stage for her work on the overuse of pesticides, the timing could not have been better. The death of hundreds of songbirds in Massachusetts as the result of aerial spraying for mosquitoes was reported to Rachel Carson by a friend in 1957. In turn, Carson called it to public attention through the media and her writings. This event was followed by a damaging spraying of a DDT–fuel oil mix over Long Island, New York, poisoning of workers and farmers in several southern states from pesticide use on fire ants, and banning of cranberries for human consumption during Thanksgiving 1959 because of pesticide use. Public furor over these incidents set the stage for the release of *Silent Spring*, and underhanded and ill-planned attempts to discredit Rachel Carson by several major chemical companies served both to canonize Carson and to identify her as the one true leader of the American environmental movement. As a result, her writings were included in the *Congressional Record* and she received an award from Secretary of the Interior Stuart Udall in 1962. President Kennedy ordered his Science Advisory Committee to investigate all of Carson’s claims. When she testified before the U.S. Congress in 1963, Rachel Carson was introduced as the person who began the environmental movement. As a result of *Silent Spring* and her advocacy, more than 40 bills were introduced to regulate pesticide use in numerous states in 1962. Carson would appear on a major nationally broadcast television special to explain the dangers of pesticides on April 3, 1963. Her death in 1964 of breast cancer was believed by many to have resulted from exposure to the chemicals she was trying to protect the public from, essentially turning her into a martyr. With time, most of the pesticides identified by Carson would indeed be banned. Al Gore, one of our most environmentally conscious politicians, recognized Rachel Carson as his inspiration toward environmentalism and the true leader of the environmental movement. *Time* magazine chose Carson as among the most influential thinkers of the 20th century.

### LASTING INFLUENCE

Rachel Carson's breakthrough work led to the creation of the field of environmental science. People's attitudes regarding air and water pollution, once thought the inevitable by-products of commercial growth and prosperity, began to change. Carson's lasting contribution was, in effect, the establishment of an environmental consciousness. The possibility of damaging the environment was not even a concept to the vast majority of Americans before Rachel Carson enlightened the American people and, indeed, people around the world. It was her influence that launched the generations of environmental scientists and advocates that have devoted their life's work to saving the planet. Although there are still numerous dangerous chemicals being produced and released into the environment today, it is a hopeful sign that many have been banned and that the dangerous concentrations once found in human breast milk have now largely been reduced. It is fitting that in 1969, the U.S. Department of the Interior changed the name of the Coastal Maine Refuge to the Rachel Carson National Wildlife Refuge and that, in 1980, President Jimmy Carter posthumously awarded Carson the Presidential Medal of Freedom, but her influence and legacy extend far beyond any medals and accolades, as a true champion of the environment.

**Castillo de Bellver oil spill Cape of Good Hope, South Africa August 6, 1983 Water Pollution** Atop a hill on the Spanish island of Majorca, about 120 miles (193 km) off the Valencian coast in the Mediterranean, is a 14th-century castle built for King James II of Majorca. Although James II did not last long as king, the castle built for him and eventually named Castillo de Bellver, or, roughly translated, Castle of the Beautiful View, survives to this

day and is one of the most popular tourist attractions on this beautiful semitropical resort island. Used as a military prison in the 1700s and 1800s, Castillo de Bellver also held loyalist prisoners during the Spanish civil war (1936–39). Although Castillo de Bellver is well known to travel agents and European vacationers, its name among commercial seafarers is more likely to provoke an image of explosions and burning oil slicks than more peaceful thoughts of sunbathing and fine wine.

### BACKGROUND

In early August 1983, the pride of the Spanish-owned Compania Arrendataria del Monopolio de Petroleos (CAMPESA) oil company's fleet of supertankers, the *Castillo de Bellver*, picked up a load of almost 2 million barrels (318 million L) of lightweight crude oil pumped from Persian Gulf fields in Murban, United Arab Emirates, and Upper Zakum, Abu Dhabi. Oil was Spain's major source of energy at this time, although its use had peaked and was now starting to decline as it was gradually being replaced by natural gas after the Organization of Petroleum Exporting Countries (OPEC) embargo of 1973. In 1985, Spain was still importing almost 40 million tons (36 million metric tons) of oil from the Middle East, which provided half of the country's energy.

As the 1,000-foot- (304.8-m-) long *Castillo de Bellver* made its way out of the Persian Gulf, through the Straits of Hormuz, and down the east coast of Africa toward the Cape of Good Hope, all seemed normal. Although not quite at the southern tip of Africa, the Cape of Good Hope, or Cape of Storms, as its discoverer Bartolomeu Dias had named it, became the halfway point for trading ships and merchantmen trying to make their way to the riches of the Middle East. The city that sprang up around the harbor 30 miles (48.3 km) north of the Cape of Good Hope, Cape Town, South Africa, was at one time nicknamed Tavern of the Seas, because this is where ships would put in and reprovision. Today, the South African government has designated the Cape and its environs as the Cape of Good Hope Nature Reserve, part of Cape Peninsula National Park. This area is widely acknowledged as habitat for extensive and diverse fauna and flora, all within a few minutes' drive of a major metropolitan center. More than 3,000 species of plants are concentrated near the tip of this continent, where the Indian and Atlantic Oceans meet. There are sand hoppers and shellfish on the beaches; 250 species of birds, baboons, antelope; and countless other varieties of small game in the reserve.

### THE ACCIDENT AND OIL SPILL

The southern tip of Africa is well known for its violent storms and especially strong winds, brought about as the warmer waters of the Indian Ocean mix with those in the cooler Atlantic. At about 2:00 A.M. on August 6, 1983, when the *Castillo de Bellver* was some 70 miles (112.7 km) west-northwest of Cape Town, it caught fire. The 31 crewmen and two passengers abandoned ship shortly after the fire began and were picked up by a local fishing trawler and a passing container ship. Three crewmen were reported missing and were never found.

The oil in the cargo holds of the *Castillo de Bellver* was a high quality crude, with a low viscosity and high vapor pressure. These physical properties of the oil resulted in its rapid ignition and dispersion into the environment. Within a few hours of the start of the fire, a burning oil slick 300 yards (274.3 m) long trailed the ship as it drifted on the currents. Smoke from the fire rose 1,000 feet (304.8 m) into the air, and farmers and ranchers later would report a “black rain” of oil droplets and soot deposited on their vineyards, wheat fields, and livestock. Salvage vessels that tried to fight the fire had to stay more than 1,000 feet (304.8 m) away because of the intense heat and flames. At around 10:00 A.M., the last of the structural members holding the ship together failed under the intense heat, and the *Castillo de Bellver* broke in two. The stern section turned over and quickly plunged 1,400 feet (426.7 m) to the ocean bottom, taking with it between 15,000 and 40,000 tons (13,608 to 36,287 metric tons) of oil.

Strong, eastward-blowing winds began to push the still-burning and leaking forward section of the *Castillo de Bellver* toward the coast, directly into Saldanha Bay and Langebaan Lagoon, a marine and wildlife sanctuary and one of the most ecologically sensitive areas of the Cape Peninsula National Park. This area of the South African coast also is an important commercial fishery, supplying more than 50 percent of the region’s rock lobster and surface, middepth, and bottom-dwelling fish and serving as a major spawning ground and nursery for those species.

By the next morning, an oil slick 20 miles (32.2 km) long and three miles (4.8 km) wide had formed, and South African officials began to fear that an ecological disaster was about to occur. LANDSAT satellite data were being used to track the slick and predict its landfall. Fortunately, two days after the spill, just as the leaking wreck and oil slick was about to make landfall on the South African coastline, the unpredictable weather of this area, just a few hundred miles north of Antarctica, changed. Winds, which had been blowing from the west-

Bellver Castle in Palma de Majorca, Spain (JCVStock; used under license from Shutterstock)

southwest and toward the shore, shifted and started to blow from the north and northwest at a steady speed of seven knots. Combined with the seaward flowing Benguela Current, the wind began to push the oil and still-burning and leaking bow section of the *Castillo de Bellver* back out to sea.

By August 7, the fire had mostly burned itself out and a tugboat was able to secure a line onto the bow section of the wrecked Spanish supertanker and drag her farther out to sea, well away from ecologically sensitive shoreline areas. After receiving permission from the ship’s owners, on August 13, South African demolition experts attached explosives to the bow section in two places and blew holes in the last floating section of the hull. The remains of the *Castillo de Bellver* sank in more than 10,000 feet (3.1 km) of water along with a cargo of an estimated 100,000 tons (90,719 metric tons) of oil. Of the 60,000 tons (54,431 metric tons) or so that are thought to have been released, 10 percent probably burned off, 40 percent evaporated, and the rest was dispersed through natural wave action or by the 60,000 gallons (234,000 L) of chemical dispersants sprayed on the landward side of the slick from aircraft and spill response vessels.

Heavy rains that had begun shortly after the fire washed the oil and soot that had blown inland off most fields. Crop damage was reported as minimal. Onshore, the most obvious impact from the spill was the oil covering about 1,500 gannets, but the majority of these were captured and released after cleaning.

### THE AFTERMATH

The large quantity of oil that had sunk with the ship, especially when the stern went down 25 miles (40.2 km) off the coast, led to a series of studies that

were conducted over the next few years to assess potential ecological impacts. At that time, it was thought that the great pressures and cold temperatures present on the seafloor would tend to solidify or immobilize the oil, although the stern section of the *Castillo de Bellver* reportedly continued to leak small amounts of petroleum for another six months. The South African government had several concerns: that the dispersed oil could have settled on the seafloor and contaminated benthic (bottom-dwelling) fauna, including fish, or fouled trawling nets, and that the area where the oil was released might have contaminated spawning grounds and caused widespread damage to fish eggs, plankton, and larvae.

Sampling surveys of water, plankton, and sediment were performed in areas where the oil slick was heaviest, where the dispersants had been applied most aggressively, and adjacent to the sunken, oil-laden stern section of the *Castillo de Bellver*. Analytical data indicated that hydrocarbon values in all three media, water, plankton, and sediment, as well as later sampling of fish eggs and larvae were within background levels. Researchers also confirmed that oil leaking from the sunken stern section of the *Castillo de Bellver* was being dispersed rapidly in the water column without observable ecological impacts.

The lack of significant ecological damage by the *Castillo de Bellver* spill was due more to good luck than to good planning. If the wind had not changed direction when it did, then it is likely that this spill, similar in size to that of the *Amoco Cadiz*, which broke apart off the French coast in 1978, would have been much more ecologically devastating and just as economically ruinous.

#### Chemical Control Corporation Elizabeth, New Jersey April 21, 1980 *Air and Soil Pollution*

The year 1980 was one of transition for the environmental movement in the United States. The U.S. Environmental Protection Agency (EPA) had been founded 10 years earlier, and the programs it had developed to reduce air and water pollution were starting to show results. Political support, however, was beginning to wane because of the short-term economic hardships that some pollution control regulations were having on industry and employment. As a result of overwhelming media focus on the Iranian hostage crisis, even Earth Day was struggling. Only about 3 million activists participated in environmental events around the country, down from 29 million in 1970. A case could be made that the public and its leaders were losing interest in the environment.

Over the next two years, however, a series of environmental catastrophes reenergized both grassroots and national political support for environmental issues. The presence and impacts of facilities that received and processed industrial wastes would emerge in the public consciousness. Places like Love Canal, Valley of the Drums, Times Beach, and Stringfellow would be added to the national lexicon and become synonymous with terror, corruption, disease, and death. This new era began with a fire on a small, two-acre (0.81 ha) parcel of land tucked into a corner of Elizabeth, New Jersey, sandwiched between the Elizabeth River and the Arthur Kill, just a few miles from New York City.

#### BACKGROUND

Between 1970 and 1978, the Chemical Control Corporation (CCC) received a wide variety of wastes intended for processing and/or storage prior to shipment to other waste disposal sites. Two small warehouses and seven chemical storage tanks, or vats, occupied the site, on reclaimed marshland at an elevation just above sea level in this heavily industrialized area of Union County, New Jersey. CCC's owners aggressively marketed their little facility and accepted all types of wastes, including acids, arsenic, bases, cyanides, flammable solvents, polychlorinated biphenyls (PCBs), compressed gases, biological agents, and pesticides. As effective as the owners were at receiving waste, they were far more ineffective at processing it. During its operation, CCC was regularly inspected by the fledgling New Jersey Department of Environmental Protection (NJDEP), which was founded only a decade earlier in 1970.

The facility was cited for numerous violations related to the storage and discharge of materials at the site. Eventually, the situation became so egregious that the state shut down the business, placing it in receivership in January 1979.

For the next 15 months, NJDEP and its contractors worked to stabilize the property. This process entailed draining and disposing of liquids from the seven aboveground storage tanks and identifying and processing about 10,000 of the more than 65,000 full and partially full drums of waste materials that were in the warehouses and stacked haphazardly around the property, sometimes in piles five to six drums high. This occurred before the Superfund program, and the state had to use its own resources to remediate the site as they were available. By the beginning of April 1980, most of the loose (noncontainerized) solids and liquids had been removed, along with a majority of the radioactive waste, highly explosive liquids, and infectious (biological) wastes.

### THE FIRE AND EXPLOSION

At about 11:00 p.m. on April 21, 1980, one day after Earth Day, a fast-moving fire broke out in one of the warehouses on the property, which held more than 20,000 drums full of waste. Its source would never be determined, but arson is suspected. Published newspaper reports and testimony by one of the owners later would claim that individuals associated with organized crime, upset by the state takeover of the property and their associated loss of revenue, started the fire. It would burn for 10 hours, and not only lit up the nearby skyline of downtown Manhattan, but also reignited an interest in the environment that would shape and define the movement for another 10 years. As a result of Chemical Control, 1980 would become known by some as the “Year of Hazardous Waste.”

When emergency crews arrived, they knew this was not a typical fire. Flames were shooting hundreds of feet into the air, and drums filled with noxious chemicals were being launched as if from cannons, exploding like fireworks high above the ground. Firefighters without respiratory protection were quickly overcome by noxious fumes, and their throats started to dry up and ache. Eventually, almost 70 people (most of them firefighters) were hospitalized with problems ranging from difficulty breathing to skin rashes.

At a distance from the fire, thousands of residents of Elizabeth, New Jersey, and Staten Island, New York, awakened by the thunderous explosions, rushed into the night and were shocked to see a

bright glowing of red, green, and yellow, depending upon which chemical was burning. As firefighters struggled to bring the four-alarm blaze under control, officials from NJDEP and the New York Police Emergency Control Board started hastily to assemble evacuation plans for the residents of Elizabeth and nearby Staten Island. Several hundred thousand people were about to be removed from hospitals, nursing homes, apartments, and houses. Luckily, three factors combined to forestall evacuation. Wind direction shifted and started to blow the mushroom-shaped cloud of contaminants that had formed directly above the CCC site to the southeast, away from populated areas and out to sea. Only a few months earlier, NJDEP had removed some of the more dangerous chemicals from the site, including 500 pounds (226.8 kg) of trinitrotoluene (TNT), as well as numerous drums of benzene, picric acid, and radioactive waste. This not only lessened the severity of the fire, but also reduced the toxicity of the smoke and ash emanating from it. Finally, the heat of the

Fire at Chemical Control Corporation drum storage yard, Elizabeth, New Jersey, April 21, 1980 (AP Images)

fire was so intense that it essentially incinerated many chemicals, rendering them much less poisonous than they might have been.

Smoke and ash from the conflagration, however, covered 15 square miles (38.9 km<sup>2</sup>) and forced the closing of schools in Elizabeth, parts of Staten Island, and several other nearby towns. Residents were urged to stay indoors for several days after the fire was extinguished, not to let young children play outdoors, and to wash down cars and lawn furniture to remove potentially contaminated dust and ash.

### THE AFTERMATH

After the fire, cleanup activities at the CCC site accelerated dramatically and became the largest emergency response action ever conducted by NJDEP. Within six months, all the firefighting apparatus was decontaminated and the remaining 49,000 drums were removed, along with more than 250,000 gallons (946,353 L) of liquid chemicals.

Eighteen months after the fire, the containers that had fallen or been launched into the Elizabeth River, both as a result of the fire and during routine site operations, were found and removed. During the operation, drums were stacked three and four high by site operators along the entire length of the riverbank. The warehouses were decontaminated and demolished, and dredging of Elizabeth River sediments, contaminated by runoff from rainwater, as well as during firefighting operations, was completed. It took another five years, however, to collect, test, and dispose of more than 200 fire-charred, unmarked gas cylinders from the site. Storm sewers damaged by heavy equipment during these remedial activities also were replaced, and several were cleaned and sealed to minimize the spread of contaminated runoff into the Arthur Kill. An earthen berm was constructed to isolate the site from the Elizabeth River and a chain link fence installed to reduce the likelihood of unauthorized persons entering the site.

For the next 18 months, NJDEP operated a groundwater remediation system to capture and treat water in the shallow aquifer, which had become highly contaminated with volatile and semivolatile organic compounds, as well as heavy metals. The contaminated soil was an even bigger problem. A variety of organic chemicals, pesticides, acid and base-neutral extractable compounds, and metals had been released during the storage and processing of waste at the site. Leachate from this soil threatened surface water and groundwater quality, as well as posing a risk to the public from airborne dust inhala-

tion and other potential exposure pathways. After reviewing the available alternatives, NJDEP decided to excavate a three-foot (1-m) layer of the most heavily contaminated soil and ship it to a treatment and disposal facility. Another 30,000 tons (27,216 metric tons) of soil was treated on-site by mixing it with a stabilizing agent that would prevent the contaminants from leaching. This soil then was used as on-site fill material and covered with an impermeable cap.

The \$26-million cost for the cleanup was staggering, especially in 1980 dollars. More than 80 percent of this money eventually was recovered from the more than 200 companies that had originally generated the waste, most of which thought they were paying to have it properly disposed of by CCC, a fully permitted and licensed waste processing facility. The final cleanup was completed in 1993, but the EPA continues to monitor the site periodically in order to confirm the effectiveness of the remedial action. The EPA assumed responsibility for the cleanup at the CCC site in late 1981, after NJDEP nominated it for inclusion in the Superfund program (National Priorities List [NPL]). Costs associated with this monitoring are estimated to be about \$60,000 per year for another 30 years. Criminal charges were filed against the owner of CCC, as well as a waste transporter who diverted truckloads of waste to the site, instead of sending them to their intended destinations. Both were found guilty and sentenced to several years in prison.

### LONG-TERM EFFECTS

The Chemical Control disaster had all the ingredients of high drama including a spectacular fire, public officials agonizing over whether to order the evacuation of one of the most densely populated parts of the United States, and mobsters conspiring to defraud millions of dollars from hundreds of companies, then trying to cover up the crime. All of these factors not only kept the Chemical Control incident in the public eye for many years, but also served a more important purpose. The fire and risk to the public at CCC were among the major incentives to force a reluctant Congress finally to act on legislation that established new regulations to control the handling and disposal of hazardous waste, as well as a fund to help states pay for the cleanup of abandoned chemical dumps. This legislation is the Comprehensive Environmental Response Compensation and Liability Act (CERCLA), better known as Superfund.

The CCC incident also helped launch the political career of Jim Florio, a congressman from New

Jersey's First Congressional District. Deeply affected by events in Elizabeth, as well as in Love Canal and other cities facing similar crises across the country, Florio authored and sponsored the CERCLA legislation and then led a tireless fight to make it law. Finally enacted on December 11, 1980, Superfund ushered in a new era of environmental protection and, for the first time, provided a vehicle for the federal government quickly and effectively to respond directly to releases or threatened releases of hazardous substances that endanger public health or the environment. Many states followed the federal government's lead and passed state-level Superfund laws, which complement and in some cases are even more stringent than CERCLA requirements.

**Chernobyl nuclear disaster Pripjat, Ukraine April 26, 1986 Air Pollution** The nuclear disaster at Chernobyl may be the most far-reaching and devastating human-caused environmental catastrophe in recorded history. The impacts of Amazonian deforestation and global warming/climate change are still being evaluated and assessed, but there is no doubt about Chernobyl's short- and long-term effects on both public health and the environment. Some 130,000 people were displaced and thousands of square miles of productive farm-

land contaminated. Beyond the 30 deaths directly attributed to the explosion and fire at Chernobyl, the health of some 5 million people has probably been compromised.

#### BACKGROUND

Located at Pripjat, Ukraine, the Chernobyl nuclear power plant was one of the largest and oldest of the Soviet Union's 15 civilian nuclear electric generating plants. It employed some 4,500 workers and was located about 80 miles (128.8 km) north of Kiev, a city with a population of 2 million. In 1986, the town of Pripjat had a population of 45,000, including 16,000 children, and was located five miles (8.1 km) from the nuclear facility. The neat little town was constructed by the Soviet Union in the 1970s with wide tree-lined streets, an amusement park, a community center, and a host of other modern conveniences for the scientists, technicians, and their families who lived there.

Four water-cooled, graphite-moderated reactors (abbreviated in Russian as RBMK, or "high-power, channel-type reactor") operated at the Chernobyl nuclear complex, and a fifth was under construction. The Soviet Union utilized RBMK reactors for a number of reasons. They are relatively inexpensive to build and operate; total plant size can be increased in modular increments as the demand for power rises; and they were able to use recycled fuel from Soviet military reactors. The RBMK reactors also had disadvantages. They tended to be unstable, susceptible to large power surges unless water coolant levels were carefully controlled. Also the more than 3,000 fuel rods used to power the reactor were not within a reinforced containment-type structure, but rather surrounded by a graphite moderator or honeycomb through which coolant flowed. Graphite has such a high heat capacity and melts at such extremely elevated temperatures that a containment building was not considered necessary. As long as the temperature of the heat produced by the fission of the uranium fuel is low and of short duration, this type of reactor can withstand an interruption in the flow of coolant. Several Western countries, including the United States, had small RBMK-type reactors being used for research purposes, but none was licensed for commercial power production.

The Soviets had designed and installed several safety features on the Chernobyl reactors. A sealed metal structure filled with inert gases surrounded each RBMK reactor to help keep oxygen away from the 1,300°F (704.4°C) graphite moderator, and extensive amounts of shielding protected plant operators from the intense radiation given off during fission.

This shielding included a concrete slab upon which the reactor rested, a sand and concrete barrier on each side of the reactor, and a large steel-reinforced concrete slab on top of the reactor. Control rods also were in use. A control rod is a solid metal bar commonly made of neutron-absorbing metals such as silver, boron, or cadmium. When removed or inserted into the reactor core, they either increase or decrease the number of neutrons being emitted by the fissionable fuel, which, in turn, changes the rate or speed of the nuclear decay process. With the control rods removed, more neutrons can bombard the fuel, more fission occurs, and more heat and steam or power is produced. Modern reactors have the control rods suspended above the core by electromagnets. If a power failure occurs, the rods automatically drop and cause a shut in a process known as a scram. This term originally was an acronym for *safety control rod ax man*. In early reactors, the control rods hung above the core suspended by a rope. In an emergency, a technician would cut the rope, and the rods would fall into the reactor and stop the fission process.

### THE ACCIDENT AND RELEASE

Some uncertainty remains as to the sequence of events that led to the disaster. It is generally agreed, however, that on April 26, 1986, at about 1:20 A.M. of the first warm, sunny Sunday of spring, reactor no. 4, which had gone online in 1983, began to reduce power in preparation for a routine operations test. The test would indicate to engineers how long the turbine and generators could run if, in some sort of emergency, the reactor shut down. For some reason, the operators turned off the reactor's primary and secondary emergency water-cooling systems. Then the power and automatic reactor shutdown systems were disconnected. Also, only about six control rods were in place, rather than the 30 required by the test procedure. This test configuration was in violation of numerous plant operational safety protocols. The Chernobyl station reportedly had a long history of plant mismanagement, poor training, and, more recently, labor unrest.

During the test, an operator's error may have caused the reactor's output to drop below a stable level, resulting in an enormous power surge. As the temperatures in the reactor increased, the fuel rods melted and burst or exploded. Realizing that the reactor was overheating, the operators activated the cooling water system. When the water had contact with the superhot melting fuel rods, a second explosion occurred, blowing the 1,000-ton (907.2-metric ton) steel cover off the reactor. The cover was attached to the fuel rods, and, once exposed, they

released fission products into the atmosphere. This explosion also threw fragments of burning fuel and graphite from the core and allowed air to rush in, causing the remaining graphite to ignite. For the next 48 hours, uncontrollable flames shot 1,000 feet (304.8 m) into the air.

It took several days to extinguish the fire and more than 10 days to stop the release of radioactivity. Most of the firefighters were plant workers, who knew that they were facing certain death either quickly in the fire or more slowly by radiation sickness. They, nonetheless, worked frantically to try to control the radiation that was pouring out of the ruined reactor building and raining down on their families and friends in nearby Pripjat. As the extent of the catastrophe became known, the Soviet government began using helicopters to drop boron, dolomite, sand, clay, and lead onto the smoldering core in an effort to limit the release of radioactive particles. It took more than 1,800 sorties and 5,000 tons (4,536 metric tons) of material eventually to stop the worst of the radiation leakage. Thirty people, including the reactor room operators, died almost immediately as a result of the explosion and fire, and, as the radiation levels began to rise, Pripjat was evacuated on May 2. Over the next 10 days, 130,000 people were forcibly relocated from their homes and farms within a 20-mile (32.2-km) radius of the reactor, now called the exclusion zone.

An airborne plume of radiation moved north with the early spring winds and contaminated more than 1 million acres (0.4 million ha) of valuable farmland in Belarus and western Russia. It then swept west across Europe, with elevated levels of radioactive fallout from the accident eventually settling across the entire Northern Hemisphere. Independent studies funded by the United Nations estimated that the amount of radioactivity released was 200 times more than from the Hiroshima and Nagasaki bombs. Millions of people in what is now Belarus, Russia, and Ukraine were exposed to varying amounts of radiation.

### RELIEF AND CLEANUP

On May 23, the Soviet government ordered the distribution of prophylactic iodine. Significant amounts of radioactive iodine were released during the accident and, since the thyroid gland cannot detect the difference between radioactive and nonradioactive iodine, it takes up the radioactive iodine in whatever proportion it is available in the environment. By ingestion of large doses of stable, nonradioactive iodine, the thyroid gland becomes saturated and will only absorb very small amounts of radioactive iodine. The delay

Destroyed reactor at Chernobyl nuclear power plant, Ukraine, April 1986 (AP Images)

in ordering the distribution of stable iodine, however, negated any positive medical effects. The radioactive iodine had already accumulated in the thyroid glands of the exposed populations.

United Nations and foreign government health services, including that of the United States, concluded that 31 people died in the accident. All were plant workers; three died directly from the explosion and 28 from radiation poisoning. More than 500 people were hospitalized, but about 5 million people were exposed to radiation from the plant. Most of the radioactive fuel and graphite was deposited close by as dust and debris, but the lighter material such as iodine 131 (half-life of eight days) and cesium 137 (Cs 137) (half-life of 30 years), which were the main fission products inside the reactor, were carried by winds and distributed more widely. In general, after 10 half-lives, a radioactive substance is considered safe for human contact. For Cs 137, this means it

will be 300 years before unrestricted use of the land can be allowed.

After the fires and worst of the radiation releases were controlled, some 200,000 people (“liquidators”) were mobilized from around the Soviet Union to assist in the cleanup. The number of liquidators working at Chernobyl later increased to more than 600,000. These volunteers, lured to Priypat by the promise of high salaries and special bonuses, worked between 1986 and 1987 to stabilize the now-demolished reactor building. In exchange for the money, they received doses of radiation averaging around 100 millisieverts (mSv). Recent studies estimate that about one in 100 people will develop cancer or leukemia from a dose of 100 mSv. Some 20,000 liquidators received radiation doses of 250 mSv, and a few were exposed to more than 500 mSv.

Within seven months after the explosive release of radioactivity at Chernobyl, an impressive-looking

**Map showing the location of Chernobyl in Ukraine and eastern Europe and the area of high radiation (shaded) from nuclear fallout. Inset map shows location in Europe.**

reinforced concrete sarcophagus was erected around the blasted and ruined structure where reactor no. 4 had once operated. Inside this hastily poured concrete shelter is about 96 percent of the reactor's nuclear fuel—an estimated 180 tons (163.3 metric tons) of uranium with a total radioactivity  $7 \times 10^{17}$  becquerel (Bq). For comparison purposes, a radioisotope (e.g., barium) used for a medical test or diagnosis contains about  $7 \times 10^7$  Bq. More than 20 years after the accident, this sarcophagus still poses great danger because of the radioactivity.

### THE AFTERMATH

The Chernobyl sarcophagus was constructed as an interim measure. It was designed to last around 20–30 years and as such was not constructed well. As a result, the concrete has shifted and cracked, and the reactor building is slowly filling with water from rain and snowmelt. This spreads the contamination internally and increases the risk of a release to groundwater. The high moisture levels also increase the rate of corrosion of main steel support beams. Although some repairs have been made, the structure itself is thought to be so unstable that a heavy windstorm or a small earthquake might cause it to

collapse. Such a catastrophic failure could result in another release of significant amounts of radioactive dust and debris. The Shelter Implementation Plan, funded by many Western countries, as well as Ukraine and Russia, is a joint design and engineering effort intended to develop a replacement for the existing Chernobyl sarcophagus. Preliminary plans call for a new 20,000-ton (17,857-metric ton) structure to cover the old sarcophagus completely. With a design life of at least 100 years, it is planned to be completed in 2012 at a cost of approximately \$1.2 billion.

After the accident, construction was halted on the two unfinished reactors. The three remaining reactors continued to operate, simply because there was no other way to supply Ukraine's electrical power needs. In 1991, fire destroyed reactor no. 2, and in 1996 reactor no. 1 was decommissioned after a deal brokered by the International Atomic Energy Agency (IAEA) to help Ukraine develop alternate energy sources. Operations at reactor no. 3 ended in December 1996.

More than 15,000 jobs were lost as a result of the accident, and it resulted in a \$12.8-billion disruption to the Soviet Union and Ukrainian economies. Some analysts credit Chernobyl as helping to contribute to the collapse of the Soviet Union. More than 6,000 people work on a daily basis at the facility on decommissioning and stabilization activities, and about 1,000 people have returned to live (unofficially) within the exclusion zone.

Studies in the early 1990s by the World Health Organization (WHO) of more than 1 million exposed people living in Ukraine, Russia, and Belarus confirmed a significant increase in thyroid cancer among exposed children. By 1995, the WHO had conclusively established that almost 700 cases of thyroid cancer including 10 deaths among children and adolescents were directly caused by radiation released from Chernobyl. Although no increase in leukemia cases apparently has occurred, the long latency period for this disease makes it likely that it will take a few more years to become statistically discernible. Similarly, there was no increase in congenital birth defects or other adverse pregnancy outcomes attributable to Chernobyl. In the region between northern Finland and the Adriatic Sea, however, miscarriage rates increased dramatically for about two years subsequent to the accident.

**chlordanne** Although the powerful insecticide chlordanne has been banned since April 14, 1988, from all uses except the treatment of fire ants in electrical transformers, it is estimated that more than 50 million Americans are exposed to it on a daily basis and most others on a regular basis. Chlordanne is one of the most persistent organic chemicals in the environment. It can remain in the atmosphere so long that it has been found all over the Pacific and Atlantic Oceans and even in the Arctic. The reason that so many Americans are directly exposed to it is that it was still permitted to be used for residential termite control even after the first ban on July 1, 1983, when all of its other applications were terminated. It was used in most homes from southern New England to California and primarily in the South built before 1988 in areas having or in danger of having termite problems. Chlordanne is also known as Velsicol 1068, Asponchlordanne, Belt, Chloridan, Chlor-kil, Cortilan-Neu, Dowchlor, Oktachlor, Oktaterr, Synchlor, Tat Chlor 4, Topichlor, Toxichlor, Intox 8, Gold Crest C-100, Kilex, Kypchlor, Niran, Termi-ded, Prentox, and Pentiklor. It has been identified as a component in 176 of the first 1,350 U.S. Environmental Protection Agency (EPA)-designated Superfund sites (on the National Priority List) in which it was tested. As a result of this widespread distribution and the adverse health effects it produces, chlordanne was ranked number 20 of the 275 most dangerous pollutants on the 2007 CERCLA Priority List of Hazardous Substances.

### PRODUCTION AND USE

Chlordanne is a synthetically created organic chemical, typically distributed as a white powder that turns into a thick colorless to amber liquid with an unpleasant chlorine odor if mixed with water. It also was available as dust, granules, concentrates, and oil solutions. Chlordanne is really a mixture of about

23 different chemicals with about 10 major components including trans-chlordanne, cis-chlordanne, beta-chlordanne, heptachlor, and trans-nonachlor. It was widely used in the United States as a pesticide from 1948 to 1988 but continued to be produced until 1996, primarily for export. Prior to 1983, the annual production of chlordanne was estimated to be about 3.6 million pounds (1.6 million kg) per year. Production strongly declined after the ban, but it is reported that the United States was still exporting 212.8 tons (200 metric tons) of chlordanne to Mexico as late as 1996. Through the years, chlordanne has had a number of applications including as a fumigating agent as well as use on corn, citrus, vegetables, fruits, and nuts; in home lawns and gardens and on ornamental plants; in turf production; and in ditch banks and on roadsides. It was used to control a variety of insects including termites, ants, parasitic roundworms and other nematodes, cutworms, chiggers, and leafhoppers, among many others, by direct application to both soil and foliage.

### ENVIRONMENTAL RELEASE AND FATE

The most common release of chlordanne into the environment was onto or into the soil. On the surface of the soil, about half evaporated in about two to three days depending upon conditions, but very little evaporated beneath the surface. Once beneath the surface, it adhered strongly to clays and organic particles in the soil and remained fixed for more than 20 years in some cases with very little leaching into the groundwater. It does not easily chemically degrade; nor is it biodegraded. In sandy soils, however, it is more mobile and may leach into the groundwater, where it has been detected in New Jersey and several other areas. The mean degradation rate has been estimated at 4.05–28.33 percent per year with an average removal half-life of 3.3 years for all soils. The highest concentration found in soils was at an EPA Superfund site where it reached 344 parts per million (ppm), and the highest groundwater concentration was 830 parts per billion (ppb). Chlordanne in surface water will evaporate at the surface with a removal half-life of 18–26 days for ponds, 3.6–5.2 days for rivers, and 14.4–20.6 days for lakes. A significant amount of the chlordanne, however, is not removed by evaporation but instead by adhering to organic and clay particles in the water and settling into the sediments. Once in the sediment, it is apparently as persistent as or more persistent than in soils. Chlordanne is greatly bioaccumulated in the aquatic environment, where fish show an average of 3,200 times ambient levels. In the atmosphere, chlordanne is primarily a vapor; it can react with hydroxyl radicals produced by photochemical reactions and be

removed with a half-life of 6.2 hours. It has been estimated, however, that 96 percent of chlordane in the atmosphere has been absorbed onto particulate matter, making it very stable and explaining the ability for long-range transport. It is then removed from the atmosphere by dry fallout or precipitation wash-out. Chlordane has been found as a component in rainwater.

The ecological effects of chlordane are variable. It is considered to be only slightly to moderately toxic to birds, although exposure is significant. It is, however, highly toxic to freshwater fish and invertebrates. Considering the bioaccumulating capacity of chlordane, it can be devastating to aquatic environments. It is also highly toxic to bees and earthworms.

### HEALTH EFFECTS FROM EXPOSURE

Chlordane is thought by some to be among the most dangerous of all environmental hazards, with health risks similar to that of cigarette smoking. It is considered to be moderately to highly toxic with acute exposure. Typically, nausea, vomiting, and abdominal pain are the first signs of chlordane exposure, but in some cases the reactions to it begin with convulsions. Central nervous system effects include initial agitation and irritability followed by depression, loss of coordination, confusion, and exhaustion. Other symptoms can be headache, dizziness, vision problems, muscle weakness and twitching, hemorrhagic gastritis, bronchopneumonia, respiratory failure, and death in high doses. It is highly irritating to the skin and eyes. Chlordane affects the liver; there fore, interactions with medicines, including anticoagulants, steroids, diphenhydramine, and birth control pills, are common.

Long-term chronic exposure of laboratory animals to chlordane primarily damaged the liver and kidneys with some damage to the central nervous system and the endocrine and immune systems. Other effects include decreased fertility by up to 50 percent; nose and eye hemorrhaging; damage to the heart, lungs, and adrenal glands in rats; and death. The EPA classifies chlordane as a group B2 probable human carcinogen. The documented expansive human exposure to chlordane allows epidemiological studies to characterize its effects more accurately than with most pollutants. The noncancerous long-term effects include gastrointestinal and neurological disorders from ingestion and sinusitis, bronchitis, dermatitis, memory loss, personality changes, attention disorders, numbness, disorientation, loss of coordination, seizures, and blood disorders simply from living in a home treated with chlordane for termites. In terms of cancer, it has been associated with increases in leuke-

mia and skin tumors in treated homes and non-Hodgkin's lymphoma among farmers. Mice contracted liver cancer from exposure. Recent studies hint at an even more sinister role for chlordane, associating it with breast cancer, immunological disorders, asthma, and a number of other life-threatening conditions. In support of some of these allegations, chlordane accumulates in human breast milk to 4.4 times the concentration of other compounds.

### REGULATIONS ON HUMAN EXPOSURE

The adverse health effects of chlordane exposure have led to several federal regulations in addition to the ban. The EPA has set a limit of 2 ppb for drinking water and recommends that no more than 60 ppb be present in drinking water that children consume for more than 10 days. Otherwise, for children it should not exceed 0.5 ppb. The EPA further requires that spills of chlordane of one pound (0.45 kg) or more must be reported to the National Response Center. The Occupational Safety and Health Administration (OSHA) limits chlordane in workplace air to 0.5 milligram per cubic meter (permissible exposure limit [PEL]) over an eight-hour-workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) has the same recommended exposure limit (REL) as OSHA and a designation of immediately dangerous to life and health (IDLH) at 500 milligrams per cubic meter. On the international level, chlordane is banned in 47 countries and severely restricted in 14 others.

**chlorinated solvents** There are a number of closely related, quickly vaporizing liquid chemicals that are very useful for a variety of industrial processes but wreak havoc when they enter the natural environment. This group, called chlorinated solvents, is produced by many of the major chemical manufacturers. Chlorinated solvents have been used for numerous purposes, including dry-cleaning operations and fluorocarbon manufacture; solvents for fats, oils, waxes, and resins; engine and parts degreasing and cleaning; and paint removal, aerosol propellants, fire extinguishers, organic synthesis, polymer manufacture, foam plastic blowing agents, adhesives solvent, and extraction of caffeine. They were formerly in very widespread use because they are excellent solvents but lack the flammability of typical solvents from hydrocarbon derivatives. The negative health effects of chlorinated solvents that have surfaced in the recent past have resulted in the phasing out of several, to be replaced with less dangerous compounds. Two chlorinated solvents methyl chloroform and carbon tetrachloride, have been implicated in causing damage to the ozone layer and have been phased out for many uses as a result.

### HEALTH EFFECTS FROM EXPOSURE

The health effects of chlorinated solvents depend upon the particular compound in question. In general, most of the solvents will cause damage to the central nervous system, liver, and kidneys, depending upon concentration and duration of exposure. They will also defat skin and cause dermatitis and other skin irritations, as well as irritation of the eyes and mucous membranes. Some chlorinated solvents can be absorbed directly through the skin, whereas others can cause rapid and erratic heartbeat. Still others are known or suspected carcinogens. Several of these solvents have relatively high vapor pressures, so they evaporate quickly. The odors from them are described as sweet smelling and pleasant. The problem is that by the time they can be detected by smell, the concentration in air is higher than the permissible exposure limit (PEL) set by the Occupational Safety and Health Administration (OSHA). Chlorinated solvents are also toxic or harmful to virtually all aquatic organisms.

### ENVIRONMENTAL RELEASE AND FATE

Chlorinated solvents are involved in countless spills and leaks to the point where only petroleum hydro-

carbon (oil) spills are more common. They have caused widespread contamination of groundwater and soil. Chlorinated solvents are commonly present as nonaqueous phase liquids (NAPLs), as dissolved contaminants in groundwater, and as vapors in the vadose zone. The density of these liquids is generally greater than that of water, making them dense non-aqueous phase liquids (DNAPLs), and, as a result, they can sink into and through the groundwater system. This property makes them subject to complex descent paths and dispersal patterns, and, even more important, they are very difficult to clean up. Recovery can be a long process with low product concentration, thus requiring heavy pumping and treatment for minimal removal. In some cases, bioremediation and/or volatilization of product has proven effective to remove them. As a result, natural attenuation may be the best alternative in many of the low-spill/leak volume or low-permeability and/or deep aquifer situations.

The following list contains a short description of the toxicity and health effects of the most common chlorinated solvents. More detailed descriptions can be found under individual compounds.

### CARBON TETRACHLORIDE

Carbon tetrachloride has a contact permissible exposure limit (PEL) of 10 parts per million (ppm) for industry workers, according to OSHA regulations, and can be absorbed through intact skin. Its potential as a carcinogen is debatable. It has been shown to cause cancer in animals and is linked to incidence of liver cancer, but other links are not well established. It can damage the kidneys, liver, and lungs and cause aplastic anemia and rapid, irregular heartbeat, which can be fatal. These negative health effects are exacerbated by alcohol. Carbon tetrachloride also causes headache, dizziness, sleeplessness, and unconsciousness, even with minor exposure.

### Chloroform

Chloroform is best known for its former use as an anesthetic in medical procedures and even in cough medicines. It is now a suspected carcinogen and is proven to cause liver and kidney damage, as well as a rapid and irregular heartbeat. It also produces unconsciousness quickly and headache, dizziness, and sleeplessness. It has a PEL of 50 ppm under OSHA regulations.

### Dichloroethylene (1,2) (DCE)

DCE has been used as an anesthetic for humans, and OSHA regulations permit a PEL of 200 ppm. It is highly flammable and can irritate skin, eyes, and

mucous membranes. It also causes headache, dizziness, and sleeplessness.

#### **Dichloroethane (1,1) (DCA)**

DCA has an OSHA PEL of 100 ppm and is highly flammable. It causes headache, dizziness, sleeplessness, and even unconsciousness at high dosage.

#### **Ethylene Dichloride**

Ethylene dichloride is among the most toxic of the chlorinated solvents and one of the few flammable compounds. It has an OSHA PEL of 1 ppm, but it is debatable as to whether it is carcinogenic. It can damage the liver, kidneys, heart, and digestive system and can irritate or damage the eyes. It also can cause headache, dizziness, sleeplessness, and unconsciousness with even small exposure.

#### **Methyl Chloroform**

Methyl chloroform is one of the least toxic of the chlorinated solvents and is not considered carcinogenic. It can, however, cause rapid and irregular heartbeat and can even be fatal in high doses. Less serious effects include skin, eye, and respiratory tract irritation and dizziness, sleeplessness, and headache. It has an OSHA PEL of 350 ppm.

#### **Trichloropropane (1,2,3)**

Trichloropropane (1,2,3) has an unpleasant odor but is not listed as a carcinogen. It has an OSHA PEL of 10 ppm.

#### **Methylene Chloride**

Methylene chloride has been used in paint removers and as such can cause painful irritation and burns of the skin and eyes. It causes liver and kidney damage, elevated blood carboxyhemoglobin, headache, dizziness, sleeplessness, and unconsciousness, depending upon the degree of exposure. It is also a suspected carcinogen and has an OSHA PEL of 25 ppm.

#### **Perchloroethylene (PCE, PERC, Tetrachloroethylene)**

Perchloroethylene has a PEL of 25 ppm for contact, according to OSHA. It is not considered to be carcinogenic, but it can affect the central nervous system causing such symptoms as headache, dizziness, sleepiness, or unconsciousness, depending upon the degree of exposure. Very high exposure can be fatal. It also can cause irritation of the skin, eyes, and upper respiratory tract.

#### **Propylene Dichloride (1,2-Dichloropropane)**

Propylene dichloride has an OSHA PEL of 75 ppm and is not considered to be a carcinogen. It can dam-

age the liver and kidneys and causes irritation of eyes, skin, and mucous membranes. It also produces headaches, dizziness, sleeplessness, and even unconsciousness at high exposure.

#### **Tetrachloroethane (1,1,2,2)**

Tetrachloroethane (1,1,2,2) has a contact PEL of 1 ppm and has the ability to be absorbed through unbroken skin. It is considered a carcinogen by the National Institute for Occupational Safety and Health (NIOSH) and can cause kidney and liver damage. Even slight exposure can cause headache, dizziness, sleeplessness, and unconsciousness. High exposure can be fatal.

#### **Trichloroethane (1,1,2)**

Trichloroethane (1,1,2) has a contact PEL of 10 ppm and can be absorbed through the skin. It is not considered to be a carcinogen, but it can cause kidney and liver damage. It is a very strong depressant, even more so than chloroform, and can cause headache, dizziness, and sleeplessness.

#### **Trichloroethylene (TCE)**

Trichloroethylene is primarily used as a vapor degreaser and has a PEL of 50 ppm. It is a suspected carcinogen and can damage the kidneys, liver, and lungs. It can also cause rapid and irregular heartbeat that can ultimately be fatal. Less serious effects include skin, eye, and mucous membrane irritation, and dizziness, sleeplessness, and headache. Use of alcohol, caffeine, and drugs of any kind greatly increases the negative effects of trichloroethylene.

**chlorobenzene** Chlorobenzene was a very important and widespread chemical in the 1950s and 1960s because it was an integral part of the production of many now-banned pesticides such as dichlorodiphenyltrichloroethane (DDT). Now it is primarily an industrial pollutant that workers are exposed to, but the general population rarely has contact with it in everyday use. The main route of exposure is, therefore, through improper handling and accidents or leakage from old landfills. Chlorobenzene also is known as benzene chloride, chlorbenzol, monochlorobenzene, phenyl chloride, IP Carrier T 40, and Tetrosin SP. Chlorobenzene has been found in 97 of the first 1,177 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List) in which it was tested. It was rated number 104 of the 275 most dangerous chemicals on the 2007 CERCLA Priority List of Hazardous Substances. It is, therefore, still considered a very dangerous substance.

### PROPERTIES, USE, AND PRODUCTION

Chlorobenzene is primarily a synthesized aromatic organic chlorinated hydrocarbon that is a colorless liquid with an almondlike odor. It is used in the manufacture of rubber, agricultural chemicals, phenol, aniline and dyes, and pigments. Previously, it was used in the manufacture of DDT. It is used as a production solvent for adhesives, paints, polishes, waxes, diisocyanates, pharmaceuticals, dry-cleaning, and rubber. It also has been utilized as a dye carrying agent and fiber swelling agent in textile manufacture, a tar and grease remover, a solvent in surface coatings, and a heat transfer medium. Chlorobenzene production in the United States has declined by more than 60 percent from its peak in 1960. Recent domestic production was 270 million pounds (127 million kg) in 1988 and 231 million pounds (105 million kg) in 1992. This decreasing trend began when DDT and other pesticides were restricted and banned and continued when chlorobenzene was regulated in 1989. This declining use is expected to continue.

### ENVIRONMENTAL RELEASE AND FATE

Chlorobenzene is released mainly from industrial facilities, from improper disposal, or from spills and

leaks during storage and transport. It is primarily a point source pollutant. It is mainly discharged through emissions and evaporation into the atmosphere, where it degenerates through reaction with photochemically generated hydroxyl radicals and photolysis. The removal half-life for this process is estimated at two to nine days. If released into surface water, most of the chlorobenzene will evaporate quickly with an estimated removal half-life of one to 12 hours if the water is rapidly flowing. If it is sequestered into the sediment at the bottom of a lake, biodegradation is the primary removal process, at a removal half-life rate of 75 days. If released into the soil, chlorobenzene will also be mainly removed by evaporation. If the soil is sandy, the remaining chlorobenzene will be mobile and leach quickly into the groundwater system. In groundwater, it degrades extremely slowly by microbial activity. In other soils, the chlorobenzene will adhere to the organic particulate and remain relatively stable. It will degrade slowly by microbial activity as a function of temperature and acclimation of the microbes. There is some evidence of moderate bioaccumulation of chlorobenzene in fish.

According to the last EPA Toxic Chemical Release Inventory, which was conducted from 1987 to 1993, more than 326,000 pounds (148,182 kg) of chlorobenzene was released into the environment by industry over this period. The state with the highest industrial environmental release of chlorobenzene is by far West Virginia, distantly followed by Ohio, New Jersey, Louisiana, and South Carolina. The industry with the highest release rate is alkalis and chlorine production, with far lesser amounts released from plastics, resins, dyes, and industrial organic chemicals.

### HEALTH EFFECTS FROM EXPOSURE

There are numerous adverse health effects from exposure to chlorobenzene. Health effects from acute exposure to chlorobenzene include skin, eye, and respiratory irritation; headaches, nausea, sleepiness, numbness, and vomiting in humans; and unconsciousness, muscle tremors, restlessness, and ultimately death in laboratory animals, depending upon the administered dosage. Long-term chronic exposure has been shown to result in muscle tremors, restlessness, increased incidence of pneumonia, and damage to the brain, spleen, liver, bone marrow, and kidneys in laboratory animals, depending upon the amount absorbed and duration of exposure. There were also reproductive effects including decreased fertility in some animals. Chlorobenzene has been shown also to increase the incidence of liver

nodules in rats, but it is not classified as a carcinogen and is considered a group D substance by the EPA, not classifiable as to its potential as a carcinogen.

### REGULATION OF HUMAN EXPOSURE

Public exposure to chlorobenzene is regulated by several federal agencies because of its adverse health effects. The EPA limits chlorobenzene in drinking water to 0.1 part per million (ppm) or less under the Safe Drinking Water Act. They recommend that short-term exposure should not exceed 2 ppm for periods up to 10 days and that levels of chlorobenzene in lakes and rivers should not exceed 0.488 ppm. Any release of chlorobenzene into the environment in amounts of 100 pounds (45.4 kg) or more must be reported to the National Response Center. The Occupational Health and Safety Administration (OSHA) set a limit of 75 ppm of chlorobenzene in workplace air over an eight-hour workday, 40-hour workweek. The National Institute of Occupational Health and Safety (NIOSH) set its immediately dangerous to life and health (IDLH) level at 1,000 ppm for chlorobenzene.

**chloroform** Chloroform is the classic anesthetic that was formerly used in medical procedures, kidnappings, and other crimes that required an unconscious victim. It has not been used for some time in medical applications, because it causes too many adverse health effects. Chloroform, also known as trichloromethane and methyltrichloride, and a synthesized organic compound within the class of chemicals called trihalomethanes is one of the chlorinated solvents. It has been sold under various trade names including Formyl trichloride, Freon 20, Methane Trichloride, Methenyl Chloride, Methenyl Trichloride, NCI-C02686, R-20, TCM, and Trichloroform. Chloroform is a colorless liquid that has a sweet odor and taste. It is nonflammable, evaporates quickly, and, in small amounts, dissolves quickly in water. It is an extremely widespread pollutant, identified in 717 of the first 1,430 EPA Superfund sites on the National Priorities List where it was tested. As a result of its widespread distribution and negative health effects, chloroform is ranked the 11th most dangerous pollutant on the 2007 CERCLA Priority List of Hazardous Substances.

### PRODUCTION AND USE

Chloroform was invented in 1831 and named in 1834. Its first application as an anesthetic was in 1847 in Europe, and it continued to be used throughout the 19th century. It was not utilized as an anesthetic in the United States until the early 20th century, and except for a few specialized procedures, this use was abandoned by the 1940s because of its many adverse effects. The first U.S. manufacturer of chloroform began production of it in 1903, but it was not commercially available until 1922. Over the years, chloroform has been sold primarily as a general solvent for a number of specialty applications including extraction and purification of some pharmaceuticals, including antibiotics, alkaloids, and vitamins, as well as flavors. As a result, it wound up in a variety of medicines and toothpastes until banned in 1976. It was also used as a solvent for lacquer, floor polish, adhesive, resins, grease and fat, gum, wax, and rubber. Chloroform also was commonly utilized as an industrial solvent for photography and dry-cleaning, a chemical intermediate for dyes and pesticides, and a transfer medium for fire extinguishers. Other applications include steel manufacturing, pesticide production, beer brewing,

building and paperboard product manufacturing, and food processing.

Currently, about 98 percent of the chloroform produced in the United States is used in the manufacture of hydrochlorofluorocarbon 22 (HCFC-22), a popular refrigerant (70 percent of usage) and intermediate in the production of fluoropolymers (30 percent). Most of the rest of the uses have been abandoned. To meet the needs of producing HCFC-22, U.S. production of chloroform increased by 20–25 percent in the early 1980s. In 1994, the United States produced 565 million pounds (256.8 million kg) of chloroform and exported 93 million pounds (42.3 million kg) from two manufacturers and 38 suppliers. By 2000, exports had increased to more than 220 million pounds (100 million kg). Chloroform production was greatly decreased over the years because HCFC-22 is a known ozone-depleting compound. It was phased out completely in 2010.

### ENVIRONMENTAL RELEASE AND FATE

Chloroform enters the environment through a number of pathways. Most of it is emitted from a variety of chemical manufacturers as well as paper mills. Leaks and spills from waste sites, storage tanks, and transfer procedures account for part of these industrial emissions and releases. It is reported that approximately 28 million pounds (12.7 million kg) was released into the environment in 1988, but emissions steadily decreased to 5.5 million pounds (2.5 million kg) by 2000. Chloroform in air from industrial processes or evaporated from liquid can settle onto the surface or be washed out in precipitation to some degree. Chloroform is also a by-product of chlorination processes. It is present in wastewater from water treatment plants, but it is also in virtually all chlorinated municipal drinking water. Chlorinated swimming pools can contain much higher levels of chloroform and pose more significant threats through both inhalation exposure and absorption through the skin than some industrial exposures.

Considering all of these sources, it is virtually ubiquitous in the environment, and almost everyone is exposed to chloroform to some degree. The ready evaporation from chloroform-containing liquids, water, and soil means that chloroform moves easily into a gaseous phase, where, once absorbed onto particulate matter or water vapor, it becomes quite stable. Eventually, it breaks down to several compounds, including phosgene and hydrogen chloride, both of which are toxic. In surface water, much chloroform evaporates into the atmosphere, but the remaining liquid is relatively stable. It is relatively

mobile in soil, where only small amounts adhere to clay and organic particles, some breaking down through microbial action and the rest passing into the groundwater system. It is also relatively stable in groundwater.

### HEALTH EFFECTS FROM EXPOSURE

There are numerous adverse effects from exposure to chloroform. The main organs that it targets are the liver, kidneys, and the central nervous system through inhalation, ingestion, and skin (dermal) absorption. Low doses may cause irritability, eye irritation, depression, stomach ailments (nausea, vomiting, and burning during urination), and lethargy. At higher exposure levels, it is a strong anesthetic causing narcosis and possible cardiac arrhythmia, which could be fatal. Long-term chronic exposure typically damages the liver and possibly the kidneys, leading to hepatitis and hepatomegaly. In mice and rats, chronic exposure to high levels produces kidney damage, sperm and testes effects, increased miscarriages, and birth defects. Chloroform is a known carcinogen for animals, causing hepatocellular carcinoma, kidney epithelial tumors, and neoplastic nodules in rats and mice and liver cancer in dogs. Studies suggest a link between long-term chloroform exposure and colon, rectal, and urinary bladder cancer in humans. As the link is still debatable, however, it is listed as a reasonably anticipated human carcinogen.

### REGULATIONS ON HUMAN EXPOSURE

The adverse health effects from exposure to chloroform have led federal agencies to impose strict regulations. The EPA has set a limit of one part per billion (ppb) of chloroform in drinking water and requires that all spills of 10 pounds (4.54 kg) or more must be reported to the National Response Center. The Occupational Safety and Health Administration (OSHA) has set a recommended limit of 50 parts per million (ppm) of chloroform in air for an eight-hour workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) set a short-term exposure limit (STEL) of 2 ppm in air for a 60-minute exposure and a designation of immediately dangerous to life and health (IDLH) for exposures of 500 ppm or more. NIOSH estimates that 215,000 workers were exposed to chloroform from 1972 to 1974 but only 95,330 from 1981 to 1983, thanks to more stringent regulations.

**chromium** It was hexavalent chromium contamination that affected the small Mojave Desert town of Hinkley, California, for which Erin Brockovich became an environmental advocate. Her story was made famous in the movie version of this well-publicized toxic tort lawsuit. Chromium is an inorganic contaminant and pollutant that has both natural and industrial sources. Chromium is one of the heavy metals common in industrialized areas and was found in an astounding 1,036 of the first 1,591 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (on the National Priorities List) for which it was tested. As a result of this widespread distribution and the health effects it produces, it is ranked the number 18 most dangerous pollutant on the 2007 CERCLA Priority List of Hazardous Substances.

**PROPERTIES, PRODUCTION, AND USES**

In addition to being a pollutant, chromium is an essential nutrient for good health and an ingredient in most vitamin supplements. The reasons for this apparent discrepancy are both the degree of exposure and the property that chromium exists

in several forms. The three most common forms of chromium are chromium (0), trivalent chromium (III), and hexavalent chromium (VI). Chromium 0 is the metallic version that is used in steel and other alloys. Chromium III is the naturally occurring variety found in the mineral chromite. It also is used in alloys, as a lining for industrial furnaces because of its high melting temperature, and in various compounds including vitamin and mineral supplements. Hexavalent chromium and some trivalent chromium are the mainstay chemicals of many industrial applications including chrome plating, dyes and pigments, leather tanning, wood preservatives, and less commonly in drilling lubricants, rust and corrosion inhibitors, textiles, and toner for copying machines. Hexavalent chromium is by far the greatest environmental hazard and one of the most dangerous.

The United States produces negligible amounts of raw chromium ore, but large quantities are recovered through extensive recycling processes. Despite these recovery and recycling efforts, imports of chromium increased from 485,000 tons (441,000 metric tons) in 2003 to 561,000 tons (510,000 metric tons) in 2007. The primary sources of chromium are South Africa (34 percent), Kazakhstan (18 percent), Zimbabwe (6 percent), and Russia (7 percent).

**ENVIRONMENTAL RELEASE AND FATE**

Chromium is released as both a point source and a nonpoint source pollutant. It is a natural component of most rocks, minerals, and soils and is ubiquitous in the environment as well as a heavy metal industrial pollutant. Chromium compounds in the atmosphere enter mostly from emissions from coal and oil-burning plants, steel mills, and chemical manufacturing plants. They primarily occur in finely disseminated dust particles that typically settle to the surface within 10 days. Tobacco smoke also contains chromium. Precipitation events speed up the settling process. If the chromium compounds settle to soil, they tend to bind strongly to the soil particles and become relatively fixed to them. Other sources of chromium in soil are the disposal of industrial chromium waste and products that contain chromium and removal of chromium from wastewater by filtration. As chromium-bearing precipitates settle into the water, a small amount of chromium may dissolve, but most remains bound to the precipitate and descends onto bottom sediments. Other sources of chromium in water are chromium-tainted wastewater from tanning, textile, and dye and pigment industries. From 1987 to 1993, some 200 million pounds (90.9 million kg) was released into the environment by industry;

most was released by industrial facilities in Texas, North Carolina, Indiana, Ohio, Utah, Arizona, Kentucky, and Pennsylvania.

### HEALTH EFFECTS FROM EXPOSURE

In terms of human health, chromium plays a dual role. Chromium III is essential for the proper uptake and metabolism of sugar, protein, and fat by the body. It is recommended by the American Dietetic Association that adults consume 115 micrograms of chromium III (commonly as chromium picolinate) per day. Chromium deficiency results in weight loss, decreased growth, problems in the nervous system, and conditions resembling diabetes. Too much chromium III, however, can be harmful, and chromium VI should be avoided altogether. Inhalation of high levels of chromium VI from vaporized chromic acid, chromium trioxide, or other compounds typically causes nose irritation, nose bleeding, nasal ulcers, and even holes in the nose and can cause serious asthmatic reactions including shortness of breath, wheezing, and coughing in people who are allergic to it. Chromium III may also cause allergic reactions, and inhalation of concentrated vapors should be avoided. Other effects from inhalation of chromium VI can include gastrointestinal problems and neurological effects. Skin contact with compounds containing concentrated chromium VI has been known to cause chemical burns including redness, swelling, rashes, and skin ulcers. Ingestion of chromium VI causes stomach distress, vomiting, ulcers, convulsions, hemorrhaging, kidney and liver damage, and, in some cases, death. Chromium VI, especially in calcium chromate, chromium trioxide, lead chromate, strontium chromate, and zinc chromate, has been classified as a known human carcinogen, greatly increasing the likelihood of lung cancer through long-term exposure.

Animal studies have suggested other potential human health problems, namely, that a high concentration of chromium VI is extremely toxic and that chromium III is moderately toxic to animals. As did humans, animals exhibited respiratory problems, gastrointestinal problems, liver and kidney problems, various forms of cancer, and death from acute and chronic exposure to chromium VI, and some problems from chromium III. They also showed immune system damage and developmental and reproductive damage. Chromium VI exposure decreases the number of offspring, decreases birth weights, increases birth defects several-thousand-fold, decreases sperm content, and causes the outer cellular layer of curved tubes in the testicles where spermatozoa is produced to degenerate. Developmental effects include skel-

etal and reproductive problems. Acute exposure to chromium III also increases birth defects in mice. Chromium accumulates at much higher levels in newborns and babies than adults. It has been shown to cross the placenta and concentrate in fetal tissue in these studies.

### REGULATIONS ON HUMAN EXPOSURE

As a result of the adverse health effects from exposure to chromium, federal agencies regulate human exposure. The EPA has set the maximal allowable level in drinking water at 0.1 part per million (ppm) (100 micrograms per liter) for both chromium III and chromium VI. For workplace settings, the Occupational Safety and Health Administration (OSHA) has set the maximal occupational exposure limit for chromium in air at 52 micrograms per cubic meter for chromium VI, 500 micrograms per cubic meter for water-soluble chromium III salts, and 1,000 micrograms per cubic meter for chromium 0 and insoluble chromium salts for an eight-hour workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) recommends an exposure limit of 500 micrograms per cubic meter for chromium (0) and (III) for a 10-hour workday, 40-hour workweek and one microgram per cubic meter for all chromium (VI) compounds. The occupations most commonly exposed to chromium are welding, chromate production, chrome plating, chrome pigment production, and leather tanning, although workers in painting, copy machine servicing, printing, cement production, and dye work may also experience risk.

**coal tar creosote** It is surprising that something so widespread as coal tar creosote could be such an environmental threat. Most people see objects containing creosote every day and have contact with them on at least a monthly basis, if not more frequently. Coal tar creosote, however, has been designated as the 23rd worst environmental threat of 275 on the 2007 CERCLA Priority List of Hazardous Substances. Typically associated with coal tar and coal tar pitch, these complex substances cause a variety of environmental problems that directly or indirectly affect human health. Unlike many of the other pollutants, the coal tar products contain numerous pollutants that affect many different ecological systems and organisms. In addition to the toxicity and capacity as a carcinogen, it is this multifront attack and distribution that make coal tar creosote and related substances so dangerous.

### PROPERTIES, USE, AND PRODUCTION

Coal tars are produced by the destructive distillation or carbonization of coal to produce coke or natural gas. Coal tar is distilled to coal tar pitch and creosote. Coal tar creosote is a black- to amber-colored, thick, oily liquid, and coal tar and coal tar pitch are black or dark brown, thick liquids with a smoky odor. Coal tars are actually complex mixtures of up to 10,000 chemical compounds, only 400 of which are recognized. However, fewer than a hundred or so common coal tar compounds (about 85 in one study) constitute up to 98 percent of those present in the environment. The primary components are polycyclic aromatic hydrocarbons (PAHs), which can make up to 90 percent, as well as cresols, phenols, naphthalene, amines, and sulfur-, oxygen-, and nitrogen-heterocyclic compounds, including dibenzofurans. Cresols exist in ortho-, meta-, and para- isomers and are considered a pollutant in themselves in addition

to their contribution to coal tar compounds. Coal tar creosote is the most common wood preservative in the United States and is used on railroad ties (70 percent), utility poles (15–20 percent), bridge and pier decking, log homes, fencing, playground equipment, and concrete marine pilings. Coal tar pitch is primarily used in aluminum smelting but can also be a component of roofing pitch, pipe coating, strengthening of refractory brick, fuel oil, lamp black, antifouling paints, die molds, coking, and steel and iron production. High-temperature coal tar is used to produce tar for road paving, naphthalene, graphite, smokeless solid fuel, benzene, and anthracene paste. Coal tar products are also used in medicine and shampoo to treat skin problems and as pesticides, animal and bird repellent, fungicide, and animal dips.

Domestic production of coal tar began in 1913, when more than 1 billion pounds (454 million kg) was produced through coke production. Coal tar production is closely tied to steel production in the United States because it is a by-product. In 1986, domestic production was 168.6 million gallons (638 million L), and, in 1987, it was 1.8 billion pounds (816 million kg). Domestic coal tar creosote distillate production was 528 million pounds (240 million kg) in 1992. In 1995, one company alone produced 92 million gallons (348 million L) of creosote.

### ENVIRONMENTAL RELEASE AND FATE

Coal tar creosote and coal tar products contain so many compounds with so many properties that release into the environment is generally complex. The main routes of exposure are in sediments, soil, and groundwater, with smaller amounts released into the air. It is mainly a nonpoint source pollutant from all the numerous everyday applications (every utility pole, roof, and road) as well as a point source pollutant from manufacturing plants, improper handling, and spills and leaks from transport and storage. In the past, wood treatment facilities discharged creosote-laden wastewater into lagoons, where it would become sludge. There are many old facilities that may contain significant amounts of highly persistent coal tar creosote and other products.

The many compounds of creosote do different things in the environment. In soil, the phenols, low-molecular-weight PAHs (those that contain three or four atomic rings), benzene, and some heterocycles may evaporate, especially upon application (tarring roofs, driveways, or roads), but once they have set and where they are not used in a liquid form, evaporation becomes a minor process. Movement within the soil is not only a function of wetness, soil chemistry, and structure but also

of molecular weight of the compounds. The high-weight compounds tend to stay fixed, whereas the low-weight compounds tend to be mobile and can leach into the groundwater system. Within the soil, biodegradation dominates reaction removal. The phenols and some heteroaromatic components are readily removed by microbial action while others are highly persistent, requiring years to tens of years for removal. Some of the breakdown products of the creosote are more mobile and toxic than the parent material. If they are released to water, a minor amount of evaporation may occur but within the water, once again, the compounds behave differently. The highly soluble fraction including the phenols, heterocyclics, and low-molecular-weight PAHs primarily dissolve, whereas the high-molecular-weight PAHs attach to particles and settle into the sediment, where they are highly persistent. Creosote can also leach from pilings in water but more so in freshwater than salt water. In addition to that which evaporates, a significant amount of creosote is released from power-plant, industry, and incinerator smokestacks. Wood creosote is released from residential fireplaces. Much of the particulate settles to the ground or is washed out by precipitation. That which persists is primarily the phenols and heterocyclics, which degrade by photochemical reactions.

Coal tar creosote is taken up to a very small degree by plants and terrestrial animals, but significant amounts can accumulate in fish and shellfish. The component that accumulates in these organisms is primarily PAH, and it is that which accumulates into sediments. Concentration factors are highly variable but as high as 73,000 times ambient levels.

### HEALTH EFFECTS FROM EXPOSURE

There are numerous adverse health effects from exposure to coal tar creosote and pitch. They may be primarily the result of PAH exposure, but benzene, naphthalene, dibenzofurans, and cresols may also be contributors. Acute exposure produces salivation, vomiting, labored breathing, vertigo, headache, delayed reflexes, hypothermia, cyanosis, and periodic to continuous convulsions followed by coma and death with increasing dosage. There can also be damage to the mouth and pharynx, intestines, pericardium, liver, and kidneys at high doses. Long-term chronic exposure can produce lesions on the skin and eyes, headache, muscle weakness, depression, confusion, vertigo, dizziness, salivation, vomiting, sensitivity to light, corneal damage, and strong allergic reactions. Coal tar creosote has also been suggested to be an endocrine disruptor and to damage

Creosote-treated logs being removed from a kiln at the Summitt Post Company, Shawnee National Forest, Winona, Missouri, ca. 1958 (CORBIS)

the immune system, as well as cause reduced fertility and birth defects.

Coal tars, pitches, and creosote are classified as U.S. Environmental Protection Agency (EPA) group B1 probable human carcinogens, and by the International Agency for Research on Cancer as group 2A probable human carcinogens for creosote and group 1 known human carcinogens for coal tars. As early as 1946, a British study found that patent fuel (a processed hard coal fuel) workers were 500 times as likely to develop scrotal cancer as the general public. Epidemiological studies of other workers exposed to coal tar pitch and creosote—from welders to millwrights to roofers—have found increased incidence of cancers of the skin (primary site), lungs, bladder, kidneys, digestive tract, oral cavity, larynx, and esophagus, as well as leukemia and brain tumors, although many of them are also exposed to other dangerous substances as well. An increase in breast and gastrointestinal cancer is suggested to result from environmental exposure to creosote. Studies on laboratory animals support the epidemiological findings showing an increase in lung and skin cancer and suggesting links to stomach and liver cancer.

The role of creosols in these health hazards is illustrated by the more acute types of symptoms caused by exposure to them. Creosols irritate the skin and eyes, producing rashes, chemical burns, and other skin problems that typically leave scars and other permanent damage. If ingested, they cause burning of the mouth, throat, and stomach, and, in high doses, they can damage the kidneys, cause unconsciousness and coma, and even result in death.

### REGULATIONS ON HUMAN EXPOSURE

The widespread distribution of this dangerous substance has led federal agencies to regulate human exposure. The EPA lists coal tar creosote as a restricted use pesticide (RUP). They also require any release of one pound (0.45 kg) or more to be reported in the National Response Center. The Occupational Safety and Health Administration (OSHA) limits the amount of coal tar pitch volatiles (permissible exposure limit [PEL]) in the workplace to 0.2 milligram per cubic meter of air per eight-hour-day, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) similarly established a recommended exposure limit (REL) for the workplace to 0.1 milligram per cubic meter of air per 10-hour-day, 40-hour workweek, and a designation of 80 milligrams per cubic meter. In the 1970s, there were about 145,000 workers involved with the production of coal tar products and 10,000 workers with coke ovens. In the 1981–83 NIOSH National Occupational Hazard Survey, it was found that there were 19,021 workers exposed to coal tar pitch, 7,677 workers exposed to coal tar pitch volatiles, and 7,274 workers exposed to coal tar.

**coastal plain deposits** Where the sea or ocean meets the land, a distinctive group of shallow water marine deposits develops and with time forms an extensive belt along the coast. The belt is a physiographic province called the coastal plain and is generally divided into the Atlantic Coastal Plain along the east coast and the Gulf Coastal Plain to the south. The coastal plain ranges from Cretaceous (140–65 million years old) to modern in age and is mostly composed of unconsolidated sediments. The basal deposits are gravels lying directly on basement rocks but vary in character and composition above them. They form the primary aquifers in these areas, and yet there is extensive industry of many kinds on them. Some of the most dangerous pollution occurs in coastal plain deposits.

### ATLANTIC COASTAL PLAIN

The Atlantic Coastal Plain extends from central New Jersey through Florida. Through most of its length it is composed of clastic sediments, but in Florida it is composed largely of carbonates. The deposits in the north are primarily beach sands, lagoon clays, local gravels, and green sands. The beach and barrier island sands are clean and well-sorted and form huge aquifers. The Kirkwood-Cohansey Aquifer of New Jersey contains trillions of gallons of clean water that is used by millions of people. The sands make up the majority of the stratigraphy of the coastal plain.

Clay deposits are much more common in the older coastal plain to the north and much more extensive in the south. They result primarily from deposition in bays and lagoons, where the water energy is very low. Extensive clay deposits are common when there is a barrier island system along the coast. The larger clay deposits are from periods when barrier islands were common. Clay was mined in the north from several geologic formations (rock types) to make pottery and other ceramics up until the early 20th century and is still mined in Georgia and other southeastern states, where it is referred to as "white gold," because it is so valuable.

There have been several periods of transgressions (rises in sea level) and regressions (drops in sea level) during the history of the Atlantic Coastal Plain. The interaction of salt water with freshwater and terrestrial deposits, and vice versa, can produce distinctive deposits. The New Jersey green sands that are mined for gardening fertilizer are an example of them. They are typically rich in phosphates, radioactive

Waves approaching the beach in Studland Bay, Dorset, England, at an oblique angle (Richard Cooke/Alamy)

elements, and fossils and rest on erosion surfaces. These layers form bands along the Atlantic Coastal Plain that can produce high levels of indoor radon and other environmental problems in houses built on them.

In Florida, the coastal plain deposits are largely limestone, although there are minor interlayered sands. The common transgressions and regressions have produced extensive phosphate deposits across Florida that are open-pit mined for agricultural fertilizer. It is the largest source of phosphates in the United States. The limestones are marked by karst topography. Limestone is so easily dissolved that there are few and only minor streams and rivers in Florida but many circular ponds and lakes filling sinkholes and leading directly into a subterranean cave system.

Pollution in the Atlantic Coastal Plain is largely around urban areas, where industrial wastes slowly infiltrate deeper and deeper into the aquifers. In many cases, the shallower groundwater cannot be used for human consumption. In agricultural areas, the fertilizers and pesticides contaminate the aquifers. In some cases, indirect pollution may result from the infiltration of fertilizer in such places as Long Island, New York, or numerous farming com-

munities in the Gulf Coast. In New Jersey, acidic fertilizer has been found to strip arsenic out of buried clay lenses within the aquifer, thus polluting the water supply. In the Floridan Aquifer of Florida, Georgia, and South Carolina, karst topography can produce a more pronounced environmental hazard. Agricultural runoff and industrial effluence enter the groundwater system directly through sinkholes and are not filtered naturally. The groundwater becomes progressively more polluted.

### GULF COASTAL PLAIN

The Gulf Coastal Plain is far thicker and more extensive than the Atlantic Coastal Plain. It extends from Texas to Florida and as far north as Tennessee along the Mississippi River. It covers the entire state of Louisiana and most of Mississippi and Alabama. It is well more than 30,000 feet (9,144 m) thick in many areas, thinning landward. Unlike the Atlantic coast, the Gulf coast is protected from the power of the Atlantic Ocean, allowing much higher volumes of sediment to accumulate. The sediments are primarily sand and shale, but there is significant salt and some limestone (including chalk) units around Florida and lesser amounts around Texas. The chief

Map of the United States with the unconsolidated sediments of the coastal plain province in green.

difference in composition between the Atlantic and Gulf coast sediments is the amount of mud and shale. The small waves in the Gulf of Mexico allow extensive deposition of mud both in deep water and near shore. The extensive sand deposits are primarily near the rivers and are well preserved in the shale.

The terrestrial sand and limestone units act as aquifers for the area. Limestone aquifers such as the Edwards Aquifer of Texas and the Floridan Aquifer of Florida are major water-bearing units. Sandstone units in Texas and Alabama are also aquifers. The difference between the Atlantic and Gulf Coastal Plains is that mud and shale produced extensive petroleum reserves in the Texas and Louisiana areas both onshore and offshore. The Gulf of Mexico is the major petroleum producing area in North America. The vast amount of petroleum withdrawn from the Gulf Coast sediments is a major economic boon to the area, but it is also very damaging to the environment. The acquisition, transportation, storage, and refining of oil present numerous opportunities for spills. Essentially all petroleum-refining products are pollutants if released into the environment. It is for this reason that the Gulf Coast is among the most polluted areas in the United States. Louisiana's "cancer alley" is a direct result of pollution caused

by the chemical industry that serves the production of petroleum by-products.

**cobalt** There are numerous inorganic metals that serve dual roles. Several (chromium, for example) are an essential nutrient and yet, at the same time, an environmental danger. Cobalt is the epitome of the natural duality. It is present in most multivitamin supplements as an essential component of vitamin B<sub>12</sub>. Cobalt sulfate was even added to animal feed and sprayed onto pastures to enhance the health and well-being of cattle, sheep, and goats with outstanding results. It is also, however, a key component in the production of "dirty bombs," which could be used by terrorists to contaminate and disrupt urban centers. One reason for the dual function of some metals is that whereas trace concentrations of many metals are essential to cellular growth and function, large quantities of the same metal can be toxic. The other reason is that cobalt exists in both a stable form,<sup>59</sup>Co, and a less stable, radioactive form,<sup>60</sup>Co. These two forms (isotopes) of cobalt have very different uses. The radioactive form is far more dangerous than the stable form. It is also much more tightly controlled, and there is far less of it in the environment. There are 426 occurrences of stable cobalt found in the first 1,636 U.S. Environmental Protection Agency (EPA)–designated Superfund sites, whereas sampling data have indicated that there are only 13 occurrences of radioactive cobalt at these same sites. As a result of the adverse health effects from exposure, cobalt is ranked number 49 of the top 275 on the 2007 CERCLA Priority List of Hazardous Substances.

### PROPERTIES, USE, AND PRODUCTION

There is evidence that cobalt was used in ceramics and jewelry for its blue color as long ago as the third millennium B.C.E. in Egypt. It was first isolated as an element in 1735, whereas the radioactive form was not isolated until 1938. Cobalt is rarely found alone but exists more commonly with ores of other metals such as nickel, copper, silver, and zinc. Cobalt-bearing minerals include cobaltite, erythrite, and skutterudite, and it is used as cobalt metal, cobalt carbonate, cobalt sulfate, cobalt sulfate heptahydrate, cobalt oxide, cobalt hydroxide, and cobalt chloride, among others. The United States produced 405,000 pounds (204,500 kg) of cobalt in 1983 but has produced very little since. Imports of cobalt increased from 9,295 tons (8,450 metric tons) in 2002 to 12,980 tons (11,600 metric tons) in 2006, primarily from Norway (21 percent), Russia (19 percent), Finland (10 percent), and China (9 percent).

Stable cobalt is primarily used in high-tech alloys for aircraft engines and other military-industrial applications, in magnets and magnetic media, as catalysts for petroleum and petrochemicals, as well as in more common applications including electroplating, grinding, and cutting tools; lithographic inks, varnishes, paints, linoleum, batteries, and electrodes; and in pigments for ceramics, enamels, glazes, and porcelain. In addition to vitamins, it is used for some specialized medicines and in replacement hip and knee joints, and it was previously used in beer brewing to stabilize the foam. Radioactive cobalt is used in industrial radiography to image flaws in metals, in food sterilization, in manufacture of plastics, and as focused radiotherapy in the treatment of brain tumors, cancer, and blood vessel irregularities.

### ENVIRONMENTAL RELEASE AND FATE

Stable cobalt is released into the environment from both natural and anthropogenic sources. It occurs in and is released by rock, soil, plants, animals, as well as windblown dust, seawater spray, volcanic eruptions, and forest fires. It is also released by dumping, wastewater, and exhaust gases from mine workings and refined ore residues; processing and smelting facilities for many metals; industries that use cobalt; coal-fired power plants; petroleum refining; incinerators; airplane and vehicular exhaust; and other commercial and industrial processes. Radioactive cobalt is released into the environment from very specific activities such as discharges from nuclear power plants and reactors, nuclear accidents, radioactive waste landfills and ocean dumping, military laboratories, and medical waste. Anthropogenic cobalt in the atmosphere is primarily from combustion and is typically attached to particulate matter that either settles or is washed out of the atmosphere by precipitation (snow or rainfall). The finer the particles, the longer the cobalt remains aloft, and it can remain in the air up to several days. Cobalt in surface water primarily sticks to particles and settles to the substrate, becoming incorporated into the sediments at the bottom of a stream or lake. In some forms, under certain conditions, cobalt may be soluble and remain as ions in water, especially if it is acidic. In soil, cobalt strongly attaches to clay and, in most cases, tends to remain immobile. In some clay-poor, acidic soils, it may be somewhat mobile and leach into the groundwater.

### HEALTH EFFECTS FROM EXPOSURE

There are several negative health effects associated with exposure to stable cobalt. Acute exposure primarily affects the lungs, resulting in wheezing,

asthma, pneumonia, congestion, edema, and lung hemorrhage. Dermal exposure also can cause skin rashes. Long-term chronic exposure also results in asthma, pneumonia, fibrosis, vision problems, immune system and thyroid damage, and congestion of the liver, kidneys, and conjunctiva. Cobalt was formerly used in beer and is implicated in increases in cardiac shock, sinus tachycardia, left ventricle failure, and other damage to the heart. People who consume large quantities of beer may have other reasons for heart problems, and the cobalt association with heart disease is regarded as questionable. Cobalt is considered a reasonably anticipated (more than likely) human carcinogen, as demonstrated by an increase in lung cancer among workers in the cobalt industries. In controlled laboratory experiments, most animals exposed to cobalt showed a distinct increase in lung tumors, and some exhibited an increase in adrenal gland cancer. Rats, guinea pigs, hamsters, and pigs exposed to high levels of cobalt also had damage to lungs, heart, liver, kidneys, and blood. Radioactive cobalt is even more dangerous. Depending upon the exposure, health effects may include nausea, vomiting, diarrhea, bleeding, coma, and even death at high levels. Long-term effects of cobalt exposure may include hair loss, blood damage, temporary sterility, genetic changes in cells, and numerous types of cancers.

### REGULATION OF HUMAN EXPOSURE

Both stable and radioactive cobalt are regulated by federal agencies. The Occupational Safety and Health Administration (OSHA) set a permissible exposure limit (PEL) of 0.1 milligram of stable cobalt per cubic meter of workplace air over an eight-hour-day, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) set their exposure limit (REL) at 0.05 milligram of stable cobalt per cubic meter of workplace air over an eight-hour-day, 40-hour workweek and a designation of immediately dangerous to life and health (IDLH) of 20 milligrams per cubic meter of workplace air. The EPA regulates exposure to radioactive cobalt to 100 picocuries per liter, or four millirems.

**continental shelf** The continental shelf is the low-lying edge of a continent that is covered by ocean water. Along those nontectonically active continental margins, where neither subduction (destruction of existing ocean crust) nor extension (formation of new ocean crust) is occurring, the shelf deepens very gradually toward the ocean and so is covered by relatively shallow water throughout its width. The width of the shelf varies by the particular continent and its plate tectonic setting. In tectonically active continental margins with subduction zones (where one plate overrides another), such as the west coast of Central and South America, the shelf is narrow to nonexistent. This is because as the plates crash against one another, the sediments that make up the margin are subducted, or dragged beneath the override plate, and into the upper mantle of the Earth. Instead, steep slopes extend offshore and lie atop highly inclined seafloors that extend into an ocean trench, the deepest places on the planet. Passive margins far from the active edges of tectonic plate collisions and spreading centers, however, such as the east coast of the United States, have wide shelves that extend several hundred miles offshore. The shelves, in these cases, give way to a more gently sloping continental slope, and then the bottom of this leading edge of the continent begins to rise gently in elevation and gradually transitions into the oceanic crust of the seafloor.

The continental shelves are the breadbaskets of the oceans. The depth of the water is so shallow on the

shelves that the photic zones, that part of the ocean through which sunlight may penetrate, extend across most of the area all the way to the seafloor. Animals and plants that depend on sunlight or on other plants and animal that depend on sunlight must live within the photic zone. In the deep ocean, this means that they can only live in the very top of the water and, therefore, must be floaters and swimmers. On the shelves, however, it means that these plants and animals can live all through the water column and even on the seafloor. This light penetration allows a completely different ecology from that of the deeper ocean. The most commonly developed ocean natural resources (oil and gas, minerals, fish, and other seafood) are from the shelves. In fact, the majority of large, commercially useful species fish (tuna, flounder, etc.) as well as other, lower-value species reside there. The resources of the shelves are critical for human survival. Unfortunately, humans tend to overuse and exploit these shelf-based resources, and the environmental health of these productive areas is in jeopardy. The overfishing and pollution have so damaged the shelves that it is unlikely they can recover without major intervention.

### POLLUTION OF THE SHELVES

Human impacts on the ecology of the shelves have been devastating. In addition to the heavy exploitation of fish and invertebrates that has led to the extinction of many species, humans have used the continental shelves as dumping grounds for waste, munitions, and other unwanted commercial and industrial debris. For years, garbage scows were loaded with refuse, towed offshore, and dumped into the ocean. Millions of tons of garbage and construction debris, among other public refuse, ended up in the ocean. The military has dumped all kinds of ordnance and other arsenal castoffs into the ocean on the shelves. On regular intervals, beaches throughout Europe are closed or restricted because live ammunition is found on them. Both the military and its contractors in Europe, the former Soviet Union, and the United States have dumped numerous barrels of nerve agent in the sea with no records kept of disposal site locations. Additionally, a number of countries have tested conventional explosive devices (bombs and rockets) over the water, causing local phosphorus pollution.

Another example of how human activities contribute to the degradation of the continental shelves

**Block diagram of the continent-to-ocean transition showing the continental shelf, the slope, and the rise: The continental shelf (a) begins a downward slant at the continental slope (b). At the foot of the slope is the continental rise (c). Submarine canyons (d) can be found in some continental slopes. Extending seaward from the continental rise is the abyssal plain.**

is the accidental and sometimes intentional release of refined and unrefined petroleum products. Oil to be delivered to refineries is often transported into ports in tankers. It is rare that tankers leak in open oceans; most accidents and oil spills happen in shallow waters closer to the ports. Although oil can eventually be degraded by bacteria, it is acutely toxic to fish and shore birds. The amount of oil that is spilled into the ocean during these accidents is staggering, and all of it ultimately affects the ecology of the shelves. The average amount spilled per year is 42.7 million gallons (162 million L), but the megaspills can involve 100–300 million gallons (380–1,140 million L) apiece.

In addition to transport accidents, a second major source of spills, not just of oil but of petrochemicals, is from oil extraction–related activities. Most oil is drilled and produced from sediments on the continental shelves, and leaks and spills from drilling and production facilities are also common. In January 1969, America watched more than 200,000 gallons (760,000 L) of oil spill into the Santa Barbara channel before the leaking well could be capped.

Much of the pollution on the shelves is delivered by rivers. The pollution, which depends upon the river and industry that it hosts, can be quite variable. A major problem is agricultural runoff in rivers. Not only can these waters contain pesticides, many of which are toxic to marine invertebrates, but they are also commonly choked with fertilizers. It was previously thought that the ocean was so big that it could absorb anything that humans could produce, but clearly this is not the case. The amount of nitrates and phosphates that the rivers and streams are delivering to the waters of the shelves is producing “dead zones,” caused by hypoxic conditions. The fertilizer introduces large amounts of nitrogen and phosphorus into the water column. These nutrients quickly stimulate indigenous bacterial and algal populations and result in massive algal blooms, which, in turn, promote the growth of bacteria that feed on the algae. The explosive growth of the algae and related bacteria rapidly depletes the oxygen in the water, which is used by these microorganisms in cellular respiration. This lack of dissolved oxygen kills all of the sessile animals and forces the mobile animals to flee. The largest dead zone is in the Gulf of Mexico and is the size of the state of New Jersey, but many other dead zones are appearing and expanding, including a large one off Chesapeake Bay and another off the Oregon coast.

Other sources of pollution to the shelves are air pollution fallout and washout. Industry and transportation in coastal regions along the eastern side of

North America and other continents produce huge amounts of air pollutants that are swept out over the ocean by prevailing winds. Considering the number of cars operating on the East Coast of the United States, the amount of nitrogen fallout into the ocean is significant, as is the particulate and sulfur from the burning of coal and other industrial sources. The entry of nitrogen into near-shore waters adds to the rampant eutrophication (depletion of dissolved oxygen due to the rapid growth of nitrogen-utilizing organisms) of the coastal regions. The same problem is becoming apparent along the east coast of China as well.

**Craney Island Hampton Roads, Virginia 1989–present Soil and Water Pollution** It was a reasonable mistake to make, especially after a three-month sea voyage in a wooden boat on the way to a strange “new world.” To the weary and nervous English settlers who sailed into Chesapeake Bay and toward the mouth of the Elizabeth River in the early 1600s, the tall, elegant birds patrolling the shore of the little island that seemed to be guarding the channel entrance looked like the cranes so commonly seen on the heaths and moors in Scotland and Wales. They named the spit of land Crayne Island, later called Crayne Point, and finally Americanized to Craney Island. The birds turned out to be white and blue herons, not cranes, and they still are regularly seen across this part of Virginia. Despite its poor taxonomical start, Craney Island turned out to be one of the most strategic points of land in the eastern United States.

#### **BACKGROUND**

Recognized early on as a military choke point, the island was quickly fortified by first the English and

later the U.S. Army. During the War of 1812, the British attacked the island but were driven off by American defenders. The victory at the Battle of Craney Island prevented the English from capturing and burning the nearby cities of Norfolk and Portsmouth, Virginia. Craney Island was also an important shipbuilding and dry-dock facility for the Confederacy during the Civil War. In 1861, using the framework of the partly burned and abandoned Union steam frigate *Merrimack*, the ironclad CSS *Virginia* was constructed at a Craney Island shipyard and sent into battle against the federal naval squadron blockading Hampton Roads. The next day, March 9, 1862, the *Virginia* engaged the USS *Monitor* in the famous Battle of the Ironclads.

By the end of World War I, Hampton Roads, the stretch of the Chesapeake Bay near its entrance to the Atlantic Ocean, was emerging as one of the premier commercial and naval ports in the country. In 1918, the U.S. Navy opened its first fuel depot on the island. Today, the four-square-mile (10.4-km<sup>2</sup>) Craney Island Fuel Terminal (CIFT), 17 miles (27.4 km) northwest of downtown Portsmouth, Virginia, is the navy's largest fueling facility in the United States. Made up of more than 1,100

acres (445 has), the facility operates more than 60 aboveground and underground storage tanks with more than 100 miles (161 km) of piping. CIFT's pier-side fuel pump stations and dispensing systems distribute more than 15 million barrels (600 million gallons or 2,271 million L) of petroleum products every year.

### CONTAMINATION OF GROUNDWATER

As a critical component in the nation's defense system, CIFT has operated continuously for almost 100 years. As have many other industrial and military facilities, it has come to recognize and is aggressively addressing a legacy of environmental issues associated with petroleum spills and releases that have occurred during the performance of its mission. These include a leak from an underground storage tank, constructed in 1953, that was cleaned and decommissioned in 1989, when the leak was detected. CIFT is working cooperatively with the Virginia Department of Environmental Quality (VDEQ) to recover the petroleum released from this tank and prevent its spread into potable groundwater or Chesapeake Bay.

USS *Milwaukee* taking on fuel at Craney Island, 1990 (Department of Defense photo, PH3 Martin Norman)

### REMEDIATION ACTIONS

Three recovery wells were installed inside the underground oil plume, and solar-powered skimmer pumps were placed inside each of these wells. A skimmer pump has a hydrophobic (water separating) membrane that rides on the top of the oil-water interface in the well. This membrane allows only petroleum to enter a special collection chamber farther down inside the pump. Once this chamber is full, sensors signal the pump to push it to the surface through a tube, where it is collected in a drum or tank for recycling. The pump is set to run at predetermined intervals to allow the slow-flowing oil to reaccumulate inside the well. Solar panels are used to recharge each system's battery pack, and a telemetry module alerts system operators when the pumps go down, the oil recovery tanks are full, or other types of maintenance are needed.

### Bioremediation

Fifteen acres (6.1 ha) of Craney Island is also being operated as a biological treatment cell (BTC) for the land farming of fuel-contaminated soil. Land farming is an *ex situ* cleanup technology that uses predominantly biological processes to treat contaminated soil. The mechanics of implementing a land farm or land application remedial system are straightforward. The contaminated soil is excavated, sometimes mixed with nutrients (fertilizers) and amendments such as lime or sawdust to adjust pH and organic carbon content, and spread out over a plastic liner. The soil is then periodically tilled (turned over) and irrigated for the next six months to two years. If suitable space is available, land farming can be done on or close to where the contamination occurred. If necessary, however, the impacted soil can be loaded and transported to a more suitable location.

Land farming relies on the activity of a wide variety of microscopic organisms that are present in all biologically active (nonsterilized) soil including bacteria, algae, fungi, protozoa, and actinomycetes. It is the bacteria that are the key to the success of land farming. Bacteria break apart the contamination in order to utilize the carbon present in the contaminant as a food source or substrate. As long as there is enough air and water to support bacterial growth, then the bacteria will attack and destroy the contamination. Land farming is not effective for all contaminants at all sites. It is usually used on soil that contains gasoline or diesel fuel, some types of wood-preserving wastes, and a few pesticides. Compounds that are nitrated or chlorinated are harder to treat via land farming because their carbon is bound up in complex molecules and is more difficult for

the bacteria to utilize. Also, the presence of excessive concentrations of total petroleum hydrocarbons (more than 50,000 parts per million [ppm]) and heavy metals (more than 2,500 ppm) may inhibit bacterial growth and severely slow or prevent significant contaminant degradation. Weather also plays a role. Bacteria work best in warm weather (more than 50°F or 10°C), and in colder climates, such as the northeastern United States, the land farming season is usually only seven to nine months long. In Virginia, the winters are milder, and land-farming operations can be carried out throughout most of the year.

At Craney Island, the land farm facility or biological treatment cell (BTC) is surrounded by a berm to stop surface runoff of oily water. The bottom of the BTC is lined with plastic, which is covered with a layer of sand. Inside this sand layer is a system of pipes designed to collect contaminated water that may infiltrate the treatment cell. A second layer of plastic covers the lower sand layer, and another layer of sand, in turn, covers that. The contaminated soil is spread out over this uppermost sand layer in lifts 12–18 inches (30.5–45.7 cm) thick. It is periodically fertilized, watered, and turned (tilled), to keep it moist and aerated and give the bacteria a chance to work. Once contaminants have dropped to acceptable levels, the soil is excavated and reused at the site.

### Phytoremediation

One-half of an acre (0.2 ha) of the BTC has been designated a phytoremediation study area. Subdivided into six plots, three different plant species (Bermuda grass sod, white clover, and tall fescue) are being evaluated for their ability to biodegrade oily contaminated soil in the rhizosphere (root zone). One plot has been left as an unvegetated control site. The process, called rhizodegradation, is based on the release into the soil of sugars from root exudate, amino acids, fatty acids, sterols, and other compounds and the stimulation or growth of bacterial populations by them. Once activated by these exudates, bacteria start to break apart the organic contaminants in order to use the carbon as substrate. The exudates act to remove nutrients, one of the more common limiting factors to bacterial growth. Given a head start, and partially sustained by root exudates, bacteria can quickly adapt and begin degrading the contaminants in the soil.

Once a month during the growing season, each plot is weeded, mowed, and fertilized. Soil samples are also collected and tested for the nutrients (nitrate, phosphorus, etc.), biomass development (weight of vegetation per square meter), total petroleum hydrocarbons (TPH), and oil in soil pore

water. After two years, TPH concentrations in the vegetated plots were found to be up to 12 percent less than in the unvegetated control plot. Rhizodegradation has been demonstrated as an effective remedial tool on some of the oiliest soils at Craney Island. No by-product wastes were produced that had to be disposed of during this remedial effort, and the cost was not much higher than for maintaining a household lawn. This developing technology offers great promise as a cost-effective and low-impact way to address petroleum-contaminated soil at some sites.

### Dredging

Since the early 1980s, the navy has aggressively pursued several innovative environmental remediation and restoration projects on Craney Island. One that serves both the environment and the local economy is the Craney Island Dredged Material Area, a 2,500-acre (1,012-ha) artificial peninsula in Norfolk Harbor. As sediment is washed into waterways making up Hampton Roads, it needs to be removed or dredged periodically to keep the shipping channels open. Dredged material is pumped into a series of special cells that allow the sand, silt, and clay to settle out and the water to be discharged. The reclaimed land is used as critical habitat for beach nesting birds such as the terns, herons, and gulls, first seen by the British settlers 300 years ago.

**Crutzen, Paul Josef (1933– )** *The Netherlands Chemist* Paul Crutzen is one of the most prominent environmental scientists in the world. His

greatest achievement was his pioneering work on the causes of depletion of the ozone layer. This work earned him the Nobel Prize in chemistry in 1995. Crutzen first proposed that oxides of nitrogen might be the cause of ozone depletion in 1970. Arising from heavy use of agricultural fertilizers and internal combustion engines, nitrogen oxides could penetrate the stratosphere, where, through a series of reactions driven by ultraviolet radiation, ozone could be dissociated, or broken into mono- and diatomic oxygen ( $O_3$  to  $O$  and  $O_2$ ). This theory became especially popular in the late 1970s, when supersonic transport (SST) aircraft were being built and were expected to replace conventional jets. SSTs fly higher than normal aircraft and introduce exhaust rich in nitrogen oxides at levels of the atmosphere where they would cause great damage. Fortunately, for economic and market reasons, large numbers of SSTs were never built or placed into service. The potential dangers from chlorofluorocarbons (CFC) would overshadow risks to the ozone layer posed by nitrogen oxide exhaust gases. Consequently, later work by Mario Molina and Sherwood Rowland on CFCs allowed them to share the Nobel Prize with Crutzen.

The second major contribution that Paul Crutzen made to environmental science was to recognize the potential for a nuclear winter in the event of an atomic war. Although Carl Sagan is credited with having proposed the potential for nuclear winter in his famous paper of 1984, Crutzen had had the idea in 1982. He thought that the explosions would ignite most vegetation as well as many structures. The massive amount of smoke generated by the fires of a nuclear war, coupled with all the dust raised by the explosions, would essentially block the Sun for years, sending the Earth into darkness. The deficit of sunlight reaching the surface of the Earth would severely decrease the temperature, thus the term *winter*. The lack of sunlight and cold temperatures would restrict the growth of biomass and set back the progress of life significantly. Whether Carl Sagan independently derived the theory or was influenced by Crutzen cannot be determined, but, in any event, Crutzen deserves the credit for formulating this theory first.

Paul Crutzen has also made some well-publicized arguments regarding global warming. He has stated that the attempts to limit the human production of greenhouse gases have no chance now of even slowing this catastrophe of global warming. Global warming has so changed the climate of the Earth that rather than continue to refer to the current geological epoch as the Holocene, as it is conventionally called, the time after the middle to late 18th century should be called the Anthropocene to reflect

the influence that humans have had on the very processes of the Earth. To address climate change, Crutzen has proposed that we need a radical contingency plan. He suggested that we inject sulfur-rich aerosol particles into the upper atmosphere to block incoming solar radiation and reflect it back into space. This proposal is given serious consideration in most discussions related to developing solutions to global warming and climate change.

Although he is not as popular as many of the scientists in the limelight such as Carl Sagan, Paul Crutzen is one of the most well-known and respected members of the scientific community. He has produced a great number of research articles (220). His influence can be measured by the number of times his work is cited in other articles. Crutzen was arguably the greatest of any environmental scientist in the world for the decade from 1991 to 2001. He had 2,911 citations of 110 of his papers over that decade and was presented an award to commemorate this feat in 2002. This reverence for his work shows how important Paul Crutzen is to the environmental community.

### BIOGRAPHICAL INFORMATION

Paul Josef Crutzen was born on December 3, 1933, in Amsterdam, the son of Anna Gurk and Josef Crutzen. In May 1940, the Nazis conquered the Netherlands, just as Paul was entering elementary school. For the next six years, his schooling was frequently interrupted by World War II. Classes were canceled or delayed or moved to different locations, as buildings they were held in were appropriated for war efforts or destroyed. The cold winter of 1944–45 was called the “winter of famine,” because of severe shortages of food, heating fuel, and water, which resulted in hunger and disease. Several of Paul’s schoolmates died as a result.

Paul Crutzen entered the Hogere Burgerschool (middle school) in 1946 and graduated in 1951, specializing in natural sciences. He then entered the Middelbare Technische School (MTS) to become a civil engineer. Upon graduation in 1954, he accepted a position as civil engineer with the Bridge Construction Bureau of the City of Amsterdam, where he remained until February 1958, when he married his wife, Terttu Soininen. For 21 months between 1956 and 1958, he served a compulsory military tour, as well. After his wedding, Paul and his new wife moved to Sweden, where he obtained a position with the House Construction Bureau of Gälve, the city in which he resided.

It was an advertised position for a computer programmer at Stockholm University that drew Paul to

academia. On July 1, 1959, Paul moved to Stockholm to accept the position in the Meteorology Institute of Stockholm University. In this new job, he helped build the first numerical weather prediction models, as well as tropical cyclone models. As part of his work, he was able to attend classes and complete a master of science degree in 1963. He continued his work toward a Ph.D., but in 1965, through participation on a project with a scientist from the United States, he became interested in ozone distribution. He pursued this direction and completed his Ph.D. in 1968, with a dissertation titled “Determination of Parameters Appearing in the Dry and Wet Photochemical Theories for Ozone in the Stratosphere.” He took a leave from his position as research associate from Stockholm University to accept a European Space Research Organization postdoctoral fellowship at Clarendon Laboratory of the University of Oxford, United Kingdom, from 1969 to 1971. He returned to Stockholm University to continue his research, ultimately earning a doctor of science degree in 1973 with a dissertation titled “On the Photochemistry of Ozone in the Stratosphere and Troposphere and Pollution of the Stratosphere by High Flying Aircraft.” At that point, he became a research professor.

In 1974, Paul Crutzen left Stockholm University to accept a position at the National Center for Atmospheric Research (NCAR) in Boulder, Colorado. He first served as a research scientist in the Upper Atmosphere Project in 1974–77 and then as senior scientist and director of the Air Quality Division in 1977–80. During this time, he also worked as a consultant at the Aeronomy Laboratory of the Environmental Research Laboratories of the National Oceanic and Atmospheric Administration (NOAA) in Boulder, Colorado, and from 1976 to 1981 as an adjunct professor at Colorado State University in Fort Collins. In 1980, he returned to Europe to accept the position of director of the Atmospheric Chemistry Division of the Max Planck Institute for Chemistry in Mainz, Germany, and became the executive director of the whole institute from 1983 to 1985. After this, he served as a part-time faculty member at several institutions including the University of Chicago, Illinois, in 1987–91; Scripps Institute of Oceanography, California, from 1992 to 2008, University of Utrecht, the Netherlands, from 1997 to 2000; and the University of Mainz, Germany, where he has been an honorary professor since 1993.

### AWARDS AND HONORS

Paul Crutzen has received numerous awards for his contributions to environmental atmospheric chem-

istry. The most prestigious of these awards is the 1995 Nobel Prize in chemistry, which he shared with Mario Molina and Sherwood Rowland for their individual contributions to the documentation of the depletion of the ozone layer. Other awards include a Special Achievement Award from the Environmental Research Laboratories of the National Oceanographic and Atmospheric Administration in 1977, the Leo Szilard Award for Physics in the Public Interest from the American Physical Society in 1985, the Tyler Prize for the Environment in 1989, the Volvo Environmental Prize in 1991, the German Environmental Prize of the Federal Foundation for the Environment in 1994, the Max Planck Forschungspreis with Mario Molina in 1994, the United Nations Environment Ozone Awards for Outstanding Contributions for the Protection of the Ozone Layer in 1995, and the Accademia dei Lincei in 1997. He was named the Rolex-Discover Scientist of the Year in 1984 and received honorary doctoral degrees from York University in Canada in 1986; Université Catholique de Louvain, Belgium, in 1992; and the University of East Anglia, United Kingdom, in 1994. He was elected to membership in several national science academies including the Royal Swedish Academy of Sciences in 1992, the U.S. National Academy of the Sciences (foreign member) in 1994, and the Russian Academy of Sciences (foreign member) in 1999.

**Cryptosporidium** *Cryptosporidium* is a resistant protozoan that is the third to fourth most widespread waterborne pathogen in the world. It was first identified in 1982 and since then has been reported in about 100 countries and every continent except Antarctica. The reported infection rates are much higher in developing countries. It was first identified in the United States during an outbreak in Braun Station, Texas, in 1984, and, since then, *Cryptosporidium* has been responsible for millions of infec-

tions throughout North America and Europe. The largest epidemic was in Milwaukee, Wisconsin, in 1993, when some 403,000 cases were documented and traced to inadequate filtration of lake water. It is the relative resistance of *Cryptosporidium* to natural degradation processes and even disinfection practices within its life cycle that make it such a potent agent of infection and public health danger.

#### SOURCES AND DISTRIBUTION

*Cryptosporidium* is a protozoan in the phylum Apicomplexa, which also includes the causative agent of malaria, and develops in the gastrointestinal tract of vertebrates throughout their life cycle. *Cryptosporidium* includes about 10 identified parasite species, which have been identified in more than 150 mammals to date. The species that infects humans is *Cryptosporidium parvum*, but a subspecies of it infects several animals, as well. The life cycle lasts from one to eight days and begins when a sporulated oocyst is ingested by a host. The sporozoites excyst in the small intestines, where the oocyst is produced. This oocyst consists of four sporozoites within a strong, multi-layered shell. The oocyst can then be excreted by the organism, whereby it enters the environment.

The thick chemically resistant wall of the oocyst does not readily decay in the natural environment or with most standard disinfection practices. It can survive for months in cool, dark soils or up to one year in cool, low-turbidity water. *Cryptosporidium parvum* oocysts are more resistant to disinfecting chemicals than most protozoa. Chlorination at drinking water levels and even pool water levels is insufficient to disinfect water of the oocysts. Freezing of water to very low temperatures (one hour at -158°F [-70°C] or 168 hours at -60°F [-15°C]) or heating it above 140°F (60°C) for five to 10 minutes neutralizes the oocysts. Drying the oocysts for one to four days also destroys their infectivity. The best method to remove oocysts from water is with a well-operated filtration system.

*Cryptosporidium* is found in raw sewage but also in surface water, groundwater, and soil. Depending upon the study, *Cryptosporidium* has been found in more than 50 percent of raw sewage samples analyzed. Groundwater varies considerably. In some studies, *Cryptosporidium* occurs in as little as 5.6 percent of the samples, whereas in others it is in up to 87.1 percent of the samples. Streams flowing through pastures and other agriculturally impacted areas have typically elevated levels, as do those streams that have potential impact of raw sewage either by direct dumping or by accidental overflows. Groundwater is typically less impacted than surface water. One study found that five percent of vertical

wells, 20 percent of springs, and 45 percent of horizontal wells were infected. These numbers are area-specific. Deep wells are less impacted than shallow wells, and developed or agricultural areas are more impacted than rural areas. The type of aquifer used is also important. Fractured rock and karst aquifers are much more susceptible to contamination by bacteria and protozoa because of their diminished filtering capacity.

### HEALTH EFFECTS FROM EXPOSURE

After exposure, incubation in humans varies between two and 10 days with the majority between seven and nine days. The main symptom is profuse, nonbloody diarrhea, which usually resolves itself in 48 hours. Other common symptoms include abdominal cramps, vomiting, lethargy, and general malaise. In some cases, *Cryptosporidium* has been linked to renal failure and liver disease, but the cause and effect relationship is not clear. It is also much more serious in patients undergoing chemotherapy for cancer, acquired immunodeficiency syndrome (AIDS) patients, infants and young children, and elderly adults.

**Cuyahoga River pollution Cleveland, Ohio 1969–present** *Water Pollution* Depending upon where a trip down the Cuyahoga River takes place, it is either wonderfully scenic or very

depressing. This 100-mile- (160.9-km-) long river in northeastern Ohio has its headwaters northeast of the 50-square-mile (129.5-km<sup>2</sup>) Cuyahoga Valley National Park, a quiet and protected area of woodlands, gentle hills, and historic farms, only a short distance from the urban centers of Cleveland and Akron. Not a particularly deep watercourse, the Cuyahoga River has an average depth of only three feet (0.9 m) or so. Fed by the 30+ inches (76.2 cm) of rain that this part of Ohio receives most years, the Cuyahoga's channel has a distinctive U shape. The meandering river's southward course bends sharply to the north near Akron, as it encounters the rocks and sedimentary debris left by the last glacial ice sheet that covered Ohio some 12,000 years ago. The character of the river changes dramatically once it begins its northward trek to Lake Erie, its ultimate discharge point.

The Cuyahoga River was charted in late July 1796, when Moses Cleaveland, a surveyor in the employ of the Connecticut Land Company, arrived at its mouth. Cleaveland walked upstream from where the Cuyahoga enters Lake Erie and found a wide, forested plain. He subdivided the surrounding area into lots, complete with streets, and started a settlement. His colleagues named the new settlement "Cleaveland" in his honor, and four of them stayed behind to serve as the new city's first inhabitants. Moses Cleaveland never returned. Although initial growth was slow (Cleaveland, now called Cleveland, had only 200 residents by the mid-1800s), its strategic location on Lake Erie, good natural harborage, and abundant supply of freshwater from the lake all eventually led to its development as one of the most prominent industrial cities in the midwestern United States. The Cuyahoga River played a major role in that development, both as a navigable waterway and as a convenient method of waste disposal.

### CONTAMINATION OF THE RIVER

By the early 1930s, the Cuyahoga had been straightened, widened, and deepened, to more than 25 feet (7.6 m), by the U.S. Army Corps of Engineers to allow the passage of bigger ships five miles (8.1 km) upriver to almost the center of downtown Cleveland. As a result of the industrialization that followed, in 1936, parts of the Cuyahoga River were so polluted that it could not be used for such common industrial purposes as cooling water or even the shipment of goods by barge. Pollutant levels were so high that the river occasionally caught fire. River fires were not uncommon in the 1890s and early 1900s, and some truly spectacular blazes occurred in other midwestern states, and even on water bodies in New York

Firemen spray water on the tug *Arizona* as a fire, started as an oil slick on the Cuyahoga River, sweeps the docks of the Great Lakes Towing Company in Cleveland, Ohio, November 3, 1952. (© Bettmann/CORBIS)

and Pennsylvania. In 1926, a portion of Baltimore Harbor caught fire, and, in the 1960s, the Buffalo River in western New York burned, and a tugboat burned and sank on the Schuylkill in Pennsylvania when it was caught in an oil slick that had been ignited.

Fires on the Cuyahoga River, however, were much more frequent and intense than on other rivers. Oil and debris in the slow-moving waters of the Cuyahoga reportedly burned in 1868, 1883, and 1887. When sparks from a tugboat landed on oil leaking from a refinery in 1916, they set off a series of massive explosions and a subsequent fire that killed five workers. That event resulted in the passage of a city ordinance prohibiting the release of oil into the river by refineries under threat of a \$10 fine. Surprisingly, not much changed as a result, and a second fire occurred in the same area a decade later, in 1922, and again in 1930. In 1936, the river caught fire once again and burned for almost a week. A survey by the fire department in 1952 found that a two-inch-thick oil slick that had spread across the entire length of the waterway, from the same refinery that had caused fires in 1912 and 1922, was one of the major fire threats in the city.

The same year, a fire started near a tugboat repair and maintenance facility on the Cuyahoga that

burned for more than six hours, with flames shooting five stories high and reportedly causing at least \$500,000 in damage (and possibly up to \$2 million) to a bridge, docks, piers, and barges. The fuel was the unused and waste oil that had been indiscriminately dumped into the river, along with large accumulations of trash and debris that would either wash in or be thrown in by nearby industries and municipalities. The steel mills and oil refineries and terminals that lined the navigable portions of the river did nothing to treat or neutralize their process wastewater discharges, often dumping unrefined or unusable petroleum hydrocarbons, acids, solvents, and other organic chemicals into the river as the most cost-effective and expedient way of dealing with these unwanted by-products. Although industry played a significant role in the destruction of the Cuyahoga as a viable ecosystem, it was not the sole culprit. The city of Cleveland also was one of the major polluters of the Cuyahoga. Cleveland and the surrounding suburbs pumped raw sewage into the river for more than a century without even an attempt at treatment. Oily runoff from roads and nutrient- (fertilizer-) rich overland flow from upstream agricultural areas also contributed significantly to the degraded water quality of the river. Ecologically, the Cuyahoga was a dead river, with one federal study unable to find

even a slight indication of the simplest form of river life, not even leaches or sludge worms that feed on wastes.

The Cleveland City Fire Department became recognized as national experts in fighting river fires. The department was equipped with several firefighting boats, and crews regularly were called out to deal with both large and small conflagrations. Prevention of these river fires became an important part of the fire department's duties, and several crews were specially trained to spot oil slicks and apply chemical dispersants to help break them up.

### PUBLIC CONCERN ABOUT POLLUTION

After the 1952 fire, business and community leaders started to pressure the city of Cleveland to address the pollution issues in the Cuyahoga River. Ten years later, in 1962, press accounts reported that the river was still clogged with debris and heavily polluted, with only the main channel being kept open for barge and river traffic. In 1963, the city contracted with a scavenger service to remove debris from the river, and several of the organizations responsible for the major point source discharges joined together to create the Cuyahoga River Basin Water Quality Committee. The committee implemented a water quality surveillance program and began to plan ways to cut down on discharges to the river.

As the 1960s came to a close, Cleveland, along with many midwestern metropolitan areas, began to lose both population and its industrial base. In addition, concern over the environment was becoming a significant force in American politics. Voters in Cleveland overwhelmingly approved a \$100-million bond issue, in late 1969, with the majority of funding dedicated to the cleanup and revitalization of the Cuyahoga River. These included major upgrades and improvements to municipal sewage treatment plants and a much more aggressive debris removal and antidumping enforcement program. Building on this momentum, a city-financed initiative was established, in early 1969, to examine ways to prevent oil from entering the river and to study ways to remove oil that was already there.

In spite of the concern, just before midday on June 22, 1969, the river caught fire again. It was not a particularly severe blaze: The oil and debris that had ignited were brought quickly under control by the fire department with only minimal damage and disruption to river traffic. This fire, however, would emerge as one of the seminal environmental events in the United States. It also would embarrass the city of Cleveland and give it a reputation as an environmental wasteland for many years to come.

### CUYAHOGA POLLUTION AS AN IMPETUS FOR CHANGE

The 1969 fire occurred just as the country was coming to grips with its need to balance business and manufacturing interests with air and water quality. The national media descended on Cleveland after the fire and, because it had been put out before local film crews could arrive, they resurrected still pictures and newsreel tapes of the much larger and more severe 1952 fire. The Cuyahoga River fire, along with the Santa Barbara oil well blowout and several other high-profile environmental disasters (such as the *Torrey Canyon* and *Argo Merchant* oil spills), would provide the impetus for much-needed federal action on environmental issues. In 1970, the U.S. Environmental Protection Agency was established, the Clean Air Act strengthened, and more than 20 million people around the country celebrated the first Earth Day.

By 1972, thanks in large part to the furor and national attention given to the 1969 Cuyahoga River fire, a revolutionary antipollution law, the Clean Water Act, was enacted. This new law, for the first time, limited the quantities and types of pollutants that could be discharged into the waters of the United States and established a national goal of making every surface water body "fishable and swimmable."

Two popular songs were written about the 1969 Cuyahoga River fire: Randy Newman's 1972 ballad *Burn On* and a 1986 song by R.E.M., titled *Cuyahoga*. The real impact of the fire, however, was to serve as a focal point, or nexus, for the environmental anxiety that many people had begun to feel. Out of this fire arose a new national resolve finally to face the air and water degradation that had been occurring across the United States as a result of more than 100 years of relatively unchecked industrial development.

### CLEANUP EFFORTS

Today, the Cuyahoga River is one of 43 Areas of Concern, or AOCs, included in the Great Lakes Water Quality Agreement. In this agreement, which tries to repair the damage done to the Great Lakes by many years of industrial and municipal misuse, the United States and Canada have decided jointly to prepare Remedial Action Plans (RAPs). These plans will propose the most technologically feasible and cost-effective methods to address beneficial use impacts on Great Lake ecosystems ranging from fish and wildlife consumption to the use of lake water for potable purposes. Of the 43 AOCs, 26 are within the borders of the United States, 12 are in Canada, and five are common to both.

The Cuyahoga River RAP is attempting to address such impacts as eutrophication, the presence of toxic substances (primarily polychlorinated biphenyls [PCBs] and heavy metals) in river water and sediment, bacterial contamination related to sanitary sewer discharges, and habitat modification caused by overdevelopment. Significant progress has been made. Fishing restrictions have been lifted in many sections of the river and habitat improvement projects, such as replacing steel bulkheads with more fish-friendly structures and removing old dams and other obstructions to improve flow and fish passage along the river, have been undertaken. Much work still remains to be done, but fish can be seen in the Cuyahoga downstream from the city of Cleveland, and water quality near where the Cuyahoga empties into the Great Lakes is improving.

**cyanide** Cyanide has a well-deserved reputation as one of the most potent poisons available. Its dark history as the active ingredient in Zyklon B, the poison gas used by the Nazis in gas chambers during the Holocaust, will never be forgotten. It was also used in the United States for many years for execution in gas chambers and as the potent suicide pill of choice for spies during World War II and the cold war. More recently, the largest mass suicide of all time occurred in Jonestown, Guyana, using a cyanide compound in a drink. With this history and reputation, any amount in the natural environment is of concern.

The devastatingly adverse health effects of exposure to cyanide have earned it the rank of the number 28 most dangerous pollutant on the 2007 CERCLA Priority List of Hazardous Substances.

#### PROPERTIES, PRODUCTION, AND USE

Cyanide is the name for a chemical group in which carbon is attached to nitrogen with three bonds (CN); it, in turn, is bonded to other elements to form cyanide compounds. Cyanides are both naturally occurring and manufactured as the result of industrial processes. The most common natural source of cyanide is from cyanobacteria, but certain algae and fungi also produce cyanide. It is found in a number of foods including almonds, lima beans, soy, spinach, and bamboo shoots, and in cassava, which is a major source of food in some countries and the source of tapioca in the United States. It can also occur in the pits of certain fruits (apples, apricots, peaches, etc.). The concentration in these sources is generally very low and creates no problems in normal exposure. A person who eats large amounts of fruit pits, however, can ingest a large enough dose to cause adverse health effects and even death. Cigarette smoke and smoke from fires (especially building fires) are more important sources of cyanide exposure. The major industrial sources of cyanide are from blast furnaces and steel production, metal heat treating, electroplating, and polishing. The production of nylon and other synthetic fibers and resins, leather tanning, paper manufacturing, certain types of mining, and, less commonly, herbicides also result in the release of cyanide. About 5 billion pounds (2.3 billion kg) of cyanide is produced in the United States each year through industrial processes. It can also be released from the incineration of municipal and medical waste. When combined with sulfur, cyanide forms the less dangerous thiocyanate group of compounds, which can be found in antibiotics, adhesives, photographic processing and photoengraving, liquid rocket fuel, and matches.

#### ENVIRONMENTAL RELEASE AND FATE

Once in the natural environment, cyanide can be a major problem. In the atmosphere, it mainly occurs as hydrogen cyanide gas with much lesser amounts in fine dust particles. It takes one to three years for one-half of the mass of released cyanide to be broken down and removed, depending upon conditions. Cyanide gas, however, is lighter than air, disperses easily, and generally will not affect the near-surface environment. In surface water, most cyanide forms hydrogen cyanide and evaporates. It does not readily

accumulate and does not bioaccumulate in fish or other aquatic life. In soil, cyanide is fairly mobile and can be removed through several processes. Some can react to form hydrogen cyanide and evaporate into the soil gas and/or escape to the atmosphere. Primarily, it is converted to other, less dangerous chemical compounds by microbial activity. Problems occur when the cyanide is in high concentrations. In this case, it can kill all of the microorganisms and then wash into the groundwater system as the result of its mobility.

### HEALTH EFFECTS FROM EXPOSURE

Cyanide is a deadly toxin. Depending upon the level of exposure, even short single doses of cyanide will result in deep breathing, shortness of breath and weakness leading to headache, vomiting, convulsions, loss of consciousness, coma, and death through cardiac edema and arrest in a matter of minutes whether it is eaten, drunk, or inhaled. It can also be absorbed through the skin, but it is absorbed much more slowly that way, and effects are less intense, although skin lesions are a common result. Even if a victim recovers from a single high dose of cyanide, often moderate to severe brain and heart damage result. Lower doses produce the early effects of a higher dose. Chronic exposure to environmental levels of cyanide can increase its concentrations in the blood. Health effects include restlessness, weakness in the fingers and toes, difficulty in walking, deafness, blurred vision, nerve damage, and decreased function of the thyroid gland. Cyanide has been shown to cause reproductive problems and birth defects in mice and rats, but no definitive connection for humans has been established, even though thyroid disease is a suspected result.

### REGULATIONS ON HUMAN EXPOSURE

Federal agencies have imposed regulations on human exposure to cyanide to address the adverse health effects. The U.S. Environmental Protection Agency (EPA) has established a limit of 0.2 part per million (ppm) of cyanide in drinking water and 50 ppm in

stored foods that have been treated with cyanide for pest control. The EPA further requires the reporting and investigation of any spill of potassium silver cyanide that exceeds one pound (0.45 kg) and the spill of hydrogen cyanide, potassium cyanide, sodium cyanide, calcium cyanide, and copper cyanide that exceeds 10 pounds (4.54 kg). The Occupational Safety and Health Administration (OSHA) set a permissible exposure limit (PEL) for hydrogen cyanide and most cyanide salts at 10 ppm for workplaces over an eight-hour workday, 40-hour workweek. The National Institute for Occupational Safety and Health (NIOSH) set a short-term recommended exposure limit (STEL) of 4.7 ppm of hydrogen cyanide in air averaged more than 15 minutes, not to be exceeded at any time during the workday. They also set the level designated as immediately dangerous to life and health (IDLH) at 50 ppm for hydrogen cyanide and most cyanide salts.

# D

**DBCP (1,2-dibromo-3-chloropropane)** DBCP was one of the most widely used nematocides and fumigants through the 1960s and 1970s. Serious adverse health effects, however, brought its use into question. One of the most famous of the adverse effects was a marked decrease in male human fertility, ranging to permanent sterility depending upon dosage. Other severe health effects were soon to be discovered and eventually resulted in legislative action to ban its usage in the United States. The first U.S. Environmental Protection Agency (EPA) ban was enacted in 1977 and enforced in 1979; it eliminated all uses except on pineapples in Hawaii. The second ban was enforced in 1985 and eliminated all remaining uses. One would think that the ban would have eliminated all human exposure, but DBCP is so persistent in groundwater that it is still present today, more than 20 years later.

DBCP is also known as BBC 12, Fumagon, Fumazone, Nemabrom, Nemafum, Nemagon, Nemanax, Nemapaz, Nemaset, Nematox, Nemazon, Gro-Tone Nematode, and Durham Nematocide. DBCP was found in only eight of the first 1,177 EPA-designated Superfund sites (National Priorities List) where it was analyzed, and yet it was rated number 44 of the 275 chemicals on the 2007 CERCLA Priority List of Hazardous Substances. It is clear from this high ranking that DBCP is a very dangerous and persistent substance.

## PROPERTIES, USES, AND PRODUCTION

DBCP is a synthetic halogenated aliphatic hydrocarbon and agricultural pesticide that does not occur in nature. It is a dense yellow to amber liquid in technical grade but was also available in emulsifiable

concentrates and granules. It was invented in 1955 and quickly became the nematocide of choice. It was primarily applied directly to soil for more than 40 different crops. Of the 32.4-million-pound (14.7-million-kg) average usage prior to 1977, approximately 12.4 million pounds (5.6 million kg) was used on soybeans, 10.5 million pounds (4.8 million kg) was used on fruit and nut groves, 3.4 million pounds (1.5 million kg) was used on vegetable crops, 3.2 million pounds (1.5 million kg) was used on peanuts, 3.2 million pounds (1.5 million kg) was used on vineyards, and 2.7 million pounds (1.2 million kg) was used on cotton fields. Other applications included golf course and residential grass, ornamental shrubs and plants, and flowers. The highest usage of DBCP was in Arizona, Hawaii, Maryland, North Carolina, South Carolina, and especially the Central Valley of California. DBCP is also still used in the production of flame retardant.

## ENVIRONMENTAL RELEASE AND FATE

As are all pesticides, DBCP was purposefully released to the environment as a nonpoint source toxicant and pollutant. Since its ban as a pesticide in 1979 and 1985, it is only released as a point source pollutant from waste and storage facilities or from the minimal manufacture for chemical applications. If released to the atmosphere, DBCP reacts with photochemically produced hydroxyl radicals and is removed, with an estimated half-life of 12.19 days. In water, DBCP will evaporate relatively quickly but react slowly. The removal half-life by evaporation ranges from 9.5 to 13.5 hours for streams and rivers but 224.2 days for lakes. In soil, DBCP will either evaporate or leach into groundwater under

most conditions. In a sandy soil, it will evaporate from the top 2.5 inches (10 cm) with an estimated half-life of 1.2 days. One study found that it could persist for up to 36 weeks in agricultural soils. Some biodegradation may occur in soil under alkaline conditions (pH of 8) at a rate of 20 percent per week. Otherwise, DBCP binds so weakly to most soils (low organic content) that it will comigrate with water into the groundwater system. Once in groundwater, it is extremely persistent, with reported removal half-lives of 38 years at 77°F (25°C) and 141 years at 59°F (15°C) under neutral pH conditions.

This extreme persistence is reflected by DBCP's being one of only five pesticides to have been consistently found in groundwater surveys throughout the United States. It was detected in 370 community water systems and 38,000 rural domestic wells in the 1990 EPA survey and in 10 percent of the 20,545 groundwater wells tested in the 1992 EPA survey. It is also persistent in some vegetables, remaining in carrots for more than 16 weeks when applied to seedlings.

### HEALTH EFFECTS FROM EXPOSURE

There are numerous serious health effects from both short- and long-term exposure to DBCP. Acute exposure by inhalation primarily affects the central nervous system, beginning with symptoms such as headache, dizziness, nausea, vomiting, and eye, nose, and throat irritation, and progressing to sleepiness, fatigue, muscle weakness and tremors, and double vision. At high dosage, tremors give way to seizures, followed by unconsciousness, coma, and death. Oral ingestion of DBCP results in pulmonary edema and shock within minutes and subsequent death depending upon dosage. Even if the victim survives, resulting brain, kidney, and/or liver damage is likely to be life-threatening. Long-term chronic exposure results in liver, kidney, spleen, eye, and bone marrow damage. It also results in loss of sperm production, the birth of more girls than boys, and permanent sterility in human males with accompanying hormone disruption. In females, there was an increased incidence of miscarriages and birth defects.

The U.S. Department of Health and Human Services has determined that DBCP is reasonably anticipated to be a human carcinogen. Animal studies reveal an increased incidence of nasal cavity, tongue, pharynx, adrenal gland, and lung cancers through inhalation exposure. Other exposure has been shown to cause cancers of the mammary glands, forestomach, stomach, kidneys, and skin. DBCP causes damage to deoxyribonucleic acid (DNA) including mutations and strand breakage in laboratory tests.

### REGULATIONS ON HUMAN EXPOSURE

In addition to the outright bans, federal agencies have imposed restrictions on public and worker exposure to DBCP. The EPA set a maximal level of 0.2 part per billion (ppb) DBCP in drinking water under the Safe Drinking Water Act. They also require the reporting of any spill of one pound (0.45 kg) or more to the National Response Center. The Occupational Safety and Health Administration (OSHA) set maximal levels of 1 ppb in workplace air for an eight-hour-workday, 40-hour workweek.

**DCB (dichlorobenzene)** Dichlorobenzene has been a very widely used industrial and, less commonly, household chemical that was strongly regulated after it was found to be a potential carcinogen. There are three isomers of dichlorobenzene, or DCB: 1,2-, ortho- or o-DCB; 1,3-DCB; and 1,4-, para-, or p-DCB. Ortho-DCB, 1,3-DCB, and p-DCB have been found in 281, 175, and 330, respectively, of the first 1,662 U.S. Environmental Protection Agency (EPA)–designated Superfund sites on the National

Priorities List. Ortho-DCB is also known as ortho-Dichlorobenzol, Dilantin, Dowtherm E, Chloroben, and Dilantin DB, and p-DCB is also known as Paradichlorobenzene, Paradichlorobenzol, Paramoth, Di-Chloricide, Paradi, Paradow, Persia-Perazol, Evola, and Parazene. As a result of its widespread distribution and adverse health effects, 1,4-DCB is ranked number 159, and 1,2-DCB is ranked number 172, on the 2007 CERCLA Priority List of Hazardous Substances.

### PROPERTIES, USES, AND PRODUCTION

Dichlorobenzenes (DCBs) are synthetic chemicals in the category of chlorinated aromatic compounds. Ortho- and 1,3-DCB are colorless to pale yellow liquids at room temperature, whereas p-DCB is a colorless to white solid with a strong, pungent odor. Para-DCB slowly changes from a solid to a vapor (sublimates) when exposed to air. Ortho-DCB and 1,3-DCB have been used to make herbicides, other agricultural chemicals, insecticides for termites and borers, medicines, coolants, degreasers and dyes and used as solvents for waxes, gums, resins, wood preservatives, and paints. Para-DCB has been used primarily as a space deodorant and as a fumigant for moth control (35–55 percent of use) as well as an insecticide on fruit and for control of mold and mildew growth on tobacco seeds, leather, and some fabrics. It also has been applied as an animal repellent and used to make dye pigments and polyethylene sulfide, a plastic for electronics products. DCB was first produced on a commercial basis in the United States in 1915. By 1986, industrial consumption of p-DCB in the United States would top 74 million pounds (33.6 million kg), and, in 1991, production of o-DCB would exceed 43 million pounds (19.5 million kg). In 1997, more than 144 million pounds (65.5 million kg) of total DCB was produced, with exports at 27.1 million pounds (12.3 million kg) by 2000 and growing by 1–2 percent per year.

### ENVIRONMENTAL RELEASE AND FATE

Besides the pesticides that may occur as nonpoint source pollutants, virtually all DCB is released as point source pollution. It is discharged mainly from industrial plants producing organic compounds, alkalis, and dyes. Release is primarily through wastewater for p-DCB and through improper handling and leaks during transport and storage, as well, for o-DCB. If released into the soil, both p-DCB and o-DCB evaporate at the surface but are moderately to tightly bound to the soil particles once they infiltrate. The presence of DCBs in groundwater sup-

plies indicates that they can leach through the soil under certain conditions. Para-DCB was found in 13 percent of surface water samples collected during a national survey. DCBs are not easily broken down by most soil organisms and not broken down at all under anaerobic conditions. DCBs do not dissolve easily in surface water, and most that enters water quickly evaporates into the air (estimated removal half-life of 4.3 hours). Some DCBs bind to particles and settle into the bottom sediment. Sediment cores from Lake Ontario contain DCBs from as early as 1940. Some DCBs that are released to groundwater may be transported through the ground to surface water. Some biodegradation occurs under aerobic conditions in surface water. DCBs released to the air are primarily in the vapor phase and degrade through reactions with photochemically produced hydroxyl radicals, with a removal half-life of 24–31 days. That which binds to particles in the air may be removed by fallout or precipitation washout. Evidence suggests that plants and fish absorb DCBs. Para-DCB has been detected at concentrations of up to 470 parts per billion (ppb) in fish, and the bioconcentration factor tends to be less than 1,000 times ambient concentration, though in some aquatic fish it can be 1,800. Trout from Lake Ontario have detectable levels of o-DCB.

The Toxic Release Inventory of 1987–1993 reported the environmental release of 248,000 pounds (112,727 kg) of o-DCB and 38,500 pounds (17,500 kg) of 1,3-DCB and 34,000 pounds (15,455 kg) of p-DCB, most of which was to water. The state with the greatest releases of o-DCB was by far New Jersey, followed distantly by West Virginia, Oregon, South Carolina, and Texas. The state with the largest releases of p-DCB was West Virginia, followed distantly by Texas, Delaware, Georgia, and Louisiana.

### HEALTH EFFECTS FROM EXPOSURE

There are numerous adverse health effects from exposure to both o-DCB and p-DCB. Acute poisoning from inhalation or ingestion of vapor or dusts of o-DCB or p-DCB at very high concentrations is characterized by disturbance of the central nervous system and kidney and/or liver damage, as well as dizziness, headaches, anorexia and nausea, irritation of the eyes, coughing, difficult breathing, and blood dyscrasias. Long-term chronic exposure to DCB has also been shown to produce adverse health effects. The effects are primarily anemia and chronic lymphoid leukemia, skin lesions, and liver damage. There is limited evidence that inhaling p-DCB decreases lung function.

Para-DCB (p-DCB) is classified as reasonably anticipated to be a human carcinogen by the International Association for Research on Cancer (IARC). It has been shown to produce an increased incidence of liver and kidney cancer in laboratory animals. It was also reported that some workers exposed to p-DCB developed an increased incidence of leukemia.

### REGULATIONS ON HUMAN EXPOSURE

As a result of these adverse health effects, federal agencies regulate human exposure to DCB. The EPA has listed o-DCB, 1,3-DCB, and p-DCB as hazardous wastes and restricts their use to hazardous waste regulations. They have set maximal levels of 60 ppb of o-DCB and 75 ppb of p-DCB in drinking water under the Safe Drinking Water Act. They also require the reporting of any spill of 100 pounds (45.5 kg) or more to the National Response Center. The Occupational Safety and Health Administration (OSHA) set maximal levels of 50 ppm for o-DCB and 75 ppm for p-DCB in workplace air for an eight-hour-workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) set its immediately dangerous to life and health (IDLH) limit to 150 ppm for p-DCB and 200 ppm for o-DCB. The EPA estimated, in 1980, that more than 1 million workers were exposed to p-DCB, and NIOSH estimated exposure of 697,803 workers during their 1971–73 National Occupational Hazard Survey.

**DCE (dichloroethene)** DCE is an industrial compound that is quite common because it is the primary component of plastic wrap, but it is also a widespread hazardous substance. Dichloroethene, or DCE, occurs in two varieties, 1,1-DCE and 1,2-DCE, the latter forming *cis*- and *trans*- isomers. DCE is also known as dichloroethylene, and for the 1,1 variety it is Asym-dichloro-ethylene, Vinylidene chloride, and Vinylidene dichloride; the 1,2-DCE variety is Acetylene dichloride, *cis*-Z-1,2-DCE, *trans*-E-1,2-DCE, and sym-DCE. The 1,1-DCE variety was found in 492 of the first 1,350 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List), where it was analyzed, and it was rated number 79 of the 275 substances on the 2007 CERCLA Priority List of Hazardous Substances. *Trans*-1,2-DCE was ranked number 173 of 275, and *cis*-1,2-DCE was ranked 270 of 275. *Cis*-1,2-DCE was found in 146 of the first 1,430 Superfund sites and *trans*-1,2-DCE was found in 563. In 336 of the sites, 1,2-DCE was found but no isomer was specified.

### PROPERTIES, USE, AND PRODUCTION

DCE is a synthetic organochloride (chlorinated hydrocarbon) that does not occur in nature. It is a highly volatile and flammable colorless liquid with a mild, sweet chloroformlike odor (1,1-DCE) or a strong, harsh odor (1,2-DCE) depending upon the variety. The 1,1-DCE variety is used in the production of polyvinylidene chloride, adhesives, synthetic fibers (textiles), refrigerants (chlorofluorocarbons), outdoor furniture, food packaging (plastic wrap), and coating resins (including flame retardant), and in chemical synthesis of a number of organic compounds. The 1,2-DCE variety is used as a solvent for dyes, perfumes, lacquers, wax, and resin; in rubber, oil, and fat extraction; as a refrigerant; and in chemical syntheses and pharmaceutical manufacture. Previously, it was used as a gasoline additive and in pesticides, cleaning solutions, paint and varnish, among others. The annual production of 1,1-DCE during the 1980s is estimated at 90,700 tons (82,450 metric tons) per year, 96 percent of which was used to produce vinyl chloride and acrylonitrile. 1,2-DCE

was produced in such small quantities that data are unavailable.

### ENVIRONMENTAL RELEASE AND FATE

1,1-DCE is largely released via spills and leaks from industrial plants and disposal or storage facilities as a point source pollutant. It is so volatile that most of the environmental release is into the atmosphere with lesser amounts into soil and water. When discharged into the atmosphere, 1,1-DCE breaks down quickly through reaction with photochemically produced hydroxyl radicals, with an estimated removal half-life of approximately 16 hours, depending upon conditions. Removal is much more rapid in polluted air (half-life of two hours) but, in any case, it is fully removed within four days. If released into the soil, most evaporates quickly with the remainder entering the soil system. Once in the soil, it is very mobile and leaches into the groundwater system, where it was found in 2.3 percent of samples taken nationwide. In groundwater, 1,1-DCE can be biodegraded to vinyl chloride, a very hazardous substance, but the process is very slow and, in most cases, insignificant. The estimated and observed removal half-life by anaerobic biodegradation ranges from one to three weeks to more than 40 weeks depending upon conditions. If released into water, most 1,1-DCE evaporates from the surface, especially if it is turbulent. Half-life removal rates are 5.9 days for a pond, 1.2 days for a river, and 4.7 days for a lake. The rest dissolves into the water, where it very slowly undergoes biodegradation. The half-life in surface water by chemical breakdown (hydrolysis) is six to nine months at pH between 4.5 and 8.5; other chemical breakdown is even slower. 1,1-DCE is also produced in the natural environment as a by-product of the anaerobic microbial breakdown of trichloroethylene (TCE), so it can be found in groundwater where no direct source exists. It is highly toxic to aquatic organisms.

1,2-DCE also evaporates readily, but it is a bit more persistent than 1,1-DCE. In air, it also reacts with hydroxyl radicals, but the removal half-life is much slower, at five to 12 days. If released into the soil, most of the 1,2-DCE will evaporate, but that which penetrates the soil is highly mobile and leaches into the groundwater system, where the removal half-life is 13–48 weeks depending upon conditions. For this reason, it has been known to migrate long distances from its source. If released into surface water, most of the 1,2-DCE evaporates, and the rest also breaks down slowly. 1,2-DCE is also produced as a natural breakdown prod-

uct of TCE and tetrachloroethylene (PCE) (among the most common groundwater contaminants) and therefore can be found in areas where there is no direct source.

It is reported that more than 11,500 pounds (5,227 kg) of 1,1-DCE was released to water (10,101 pounds [4,591 kg]) and land (1,488 pounds [676 kg]) during the 1987–93 EPA Toxics Release Inventory. The top three states for release were Kentucky, Texas, and Louisiana, primarily from the plastics and chemical industries. While the majority of the releases of 1,2-DCE occur within the Gulf Coast region of the United States, the total quantities emitted are fairly low.

### HEALTH EFFECTS FROM EXPOSURE

There are numerous adverse health effects from exposure to both 1,1-DCE and 1,2-DCE (both isomers). Acute exposure to 1,1-DCE results in central nervous system depression that may quickly progress to unconsciousness. Dermal exposure causes irritation, and prolonged exposure can produce first-degree burns. Eye exposure to 1,1-DCE causes irritation and possible conjunctivitis and transient corneal injuries. Long-term chronic exposure to 1,1-DCE causes liver, kidney, and immune system damage and possible birth defects and reproductive problems. The EPA classified 1,1-DCE as group C, possible human carcinogen. Some laboratory animals experienced increased incidence of cancer of the kidneys, lungs, lymph glands, and mammary glands. Experimental studies showed that 1,1-DCE can cause genetic mutations in microorganisms but not in mammalian cells.

Exposure to 1,2-DCE on an acute basis causes eye irritation, nausea, dizziness, fatigue, and sleepiness. At high dosage, it may cause unconsciousness, lung and liver damage, and death of heart failure. Long-term, chronic exposure may also damage the liver, lungs, heart, and circulatory system, as well as cause delayed fetal development. 1,2-DCE is classified as a group D compound by the EPA, not classifiable as to human carcinogenicity. The Department of Health and Human Services, however, determined that it is reasonably expected to cause cancer. This determination was based on a single study that found an increase in lung cancer. Other, similar studies did not connect 1,2-DCE with an increased risk of lung cancer.

### REGULATIONS ON HUMAN EXPOSURE

Federal agencies regulate exposure to DCE because of the adverse health effects. The EPA lists 1,1-DCE,

*cis*-1,2-DCE, and *trans*-1,2-DCE as hazardous wastes and restricts their use to hazardous waste regulations. They have set maximal levels of seven parts per billion (ppb) of 1,1-DCE, 70 ppb of *cis*-1,2-DCE, and 100 ppb of *trans*-1,2-DCE in drinking water under the Safe Drinking Water Act. It is recommended not to exceed 3 ppb in surface water bodies. They also require the reporting of any spill of 100 pounds (45.5 kg) or more of 1,1-DCE and 1,000 pounds (454 kg) or more of 1,2-DCE to the National Response Center. The Occupational Safety and Health Administration (OSHA) set maximal levels of one part per million (ppm) for 1,1-DCE and 50 ppm for 1,2-DCE in workplace air for an eight-hour workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) set its exposure limit to 1 ppm for 1,2-DCE in workplace air and its immediately dangerous to life and health (IDLH) limit to 3,000 ppm for 1,1-DCE and 1,000 ppm for 1,2-DCE.

**DDT (dichlorodiphenyltrichloroethane)** DDT is the most infamous of the pesticides, and the environmental and public health furor resulting from its overuse and misuse significantly fueled the beginnings of the environmental movement that eventually helped to ban it. DDT was invented in 1874, but its effectiveness as an insecticide was not discovered until 1939. Interestingly, Paul Muller, the first person to use DDT as a pesticide, was later awarded the Nobel Prize for his work, even though an African American had made the same discovery years earlier. DDT is one of a group of similar pesticides that were considered to be among the most beneficial substances developed by humans. During the 1940s and 1950s, it was used to control insect-borne typhus and malaria, helping to eradicate malaria-carrying insects from Europe and North America and virtually eliminating lice that carried the typhus bacterium. As a result, mortality rates were reduced 20-fold in a number of locations. Many other insect pests were also reduced, eliminated, or controlled by DDT, and, for decades, it became the insecticide of choice for agricultural applications. With time, many insects would become resistant to DDT, but, by then, environmental concerns related to its bioaccumulation and biomagnifications in the food web would have already heralded its decreasing popularity and ultimate ban.

It was the observations of the negative effects of DDT on wildlife in Nassau County, Long Island, New York, that caught the attention of the naturalist Rachel Carson in the mid-1950s. She and a group of colleagues would battle industry and the government for decades to ban DDT. It is this struggle that led her to write her best-selling book *Silent Spring*, which was a milestone in the establishment of the American environmental movement.

DDT, and its breakdown products, DDE and DDD, have been found in 442 of the first 1,613 U.S. Environmental Protection Agency (EPA)-designated Superfund sites (National Priorities List), which is a very high number for a pesticide. Even though it has been banned since 1972, DDT is still ranked the 12th worst pollutant of the top 275 on the 2007 CERCLA Priority List of Hazardous Substances. The breakdown products DDE and DDD are ranked numbers 21 and 25, respectively. It is because of this widespread distribution and the impressive persistence of DDT that it earned and continues to earn such a high rank.

#### ENVIRONMENTAL TOXICITY

DDT and the related chemicals DDE (dichlorodiphenyldichloroethylene) and DDD (dichlorodiphenyldichloroethane) have been studied for toxicity

more than any other pesticide and perhaps any other environmental hazard, and yet for most health effects, the data are inconclusive. They are certainly health hazards to insects, killing them by exploiting sodium ion channels in the neurons of insects, causing spasms and ultimately death. In animals, short exposures to high concentrations strongly affected the nervous system and the reproductive system, whereas long-term exposure affected the liver. Some studies showed that DDT can cause liver cancer in animals. When mice are exposed to DDT immediately after birth, they commonly have neurobehavioral problems when they are older. DDE in male rats can delay the onset of puberty. It is highly toxic to most aquatic species such as crayfish, shrimp, and many types of fish, in addition to accumulating in the fatty tissue of many others. The problem for animals in the wild is that DDT and its metabolite, or breakdown product, DDE biomagnify (increase in concentration) up the food chain. Probably the best-known effect of the biomagnification was on birds of prey, which sit at the top of the natural food chain. As a result, their reproductive capacity was diminished, and their eggshells were reported to be thinner than normal, ultimately leading to a decline in their numbers during the 1950s and 1960s. Other birds, lower in the food chain, may or may not be affected by exposure to DDT.

### HUMAN HEALTH EFFECTS FROM EXPOSURE

Reports of the toxicity of DDT to humans are conflicting. DDT affects the human nervous system by inducing excitability, tremors, and seizures with high dosage. These effects dissipate quickly, and long-term exposure appears to have no ill effects. It has been shown to affect the liver in some cases. DDE tends to be concentrated in breast milk and reduces lactation. It can also cause premature births. Several studies have suggested that DDT could cause breast cancer, but several others dispute this finding, leaving its potential as a carcinogenic agent inconclusive. As a result of these health effects, the Occupational Safety and Health Administration (OSHA) restricts workplace exposure to 1 milligram of evaporated DDT per cubic meter of air for an eight-hour shift, 40-hour workweek.

### ENVIRONMENTAL RELEASE AND FATE

Previously, DDT was primarily a nonpoint source pollutant that was applied to agricultural and landscaped properties. Currently, however, it enters the environment in the United States only through release from residual concentrations, as it has been

banned since 1972. It is still used in some countries, however. DDD and DDE enter the environment as breakdown products of DDT. All three break down quickly in sunlight with half of the mass not detectable within two days of exposure. They do not dissolve easily in water, so this is by far the most common form of natural attenuation. If DDT enters soil, it strongly adheres to the particles. It is degraded into DDD and DDE by microorganisms at the rate of conversion of half of the mass in two to 15 years, depending upon conditions. Badly tainted soil must be removed and disposed of or washed, depending upon its concentration of DDT.

### POLITICS OF DDT

In the mid- to late 1960s, DDT became more of a political issue than a real health threat. When it was banned in the United States in 1972, there were far worse substances being disposed of in the environment in large quantities. Public pressure in reaction to Rachel Carson's book *Silent Spring* was the whole impetus to ban DDT, even though the book contains then-unsubstantiated claims to its cancer-causing potential. The first administrator of the EPA, William Ruckelshaus, initially fought the ban but was later pressured into enacting it. It was a great political victory for the fledgling environmental movement in the United States. Opponents of the ban claim that it has killed more people than Hitler by allowing malaria and other insect-borne diseases to proliferate. It is true that DDT has saved literally hundreds of millions of human lives. DDT, however, is not as effective in tropical climates, which have been the primary battleground against insect-borne diseases over the past half-century. Additionally, many insects have become resistant to DDT, making it less effective. Even if DDT had not been banned, new pesticides would have had to be developed, and DDT would have had to be phased out anyway. The ban on DDT may be more symbolic than the dire necessity it was portrayed to be.

**dead zone** Eutrophication of freshwater water bodies is well known and widespread. The oceans were traditionally considered to be too large and well circulated to be affected by eutrophication processes. That belief was disproved in the 1960s when a "dead zone" developed in the Black Sea in the USSR. It was called a dead zone because developing hypoxic (oxygen-deficient) conditions suffocated all of the sessile fauna, as well as those with limited mobility, and drove off the mobile fauna leaving an area with few to no fauna. The cause of the problem was excessive agricultural fertilization around the Black Sea. Runoff from these areas after precipitation events flooded all the streams leading into the Black Sea with nutrients. These nutrients, primarily nitrogen (in nitrates) and phosphorus, triggered blooms of phytoplankton, which form the bottom of the food chain. In response to the increased food supply, zooplankton proliferated. When the phytoplankton and zooplankton died, they sank below the photic zone, where, in turn, bacteria proliferated from the increase in food supply and exhausted all of the oxygen in the water. The dead zone, therefore, began in the central part of the water column, spreading both deeper and shallower with time. In these growing dead zones, oxygen concentrations are <0.5 part per million (ppm), in comparison with fully oxygenated seawater, which contains 10 ppm.

### DEAD ZONE DISTRIBUTION

After the initial discovery of dead zones, others were soon detected. The most famous dead zone is in the Gulf of Mexico at the mouth of the Mississippi River. It is about the size of New Jersey, some 7,812 square miles (20,000 km<sup>2</sup>), and expands and shrinks depending upon the season. By 2004, 146 dead zones were reported throughout the world, with the largest measuring some 27,343 square miles (70,000 km<sup>2</sup>). By 2006, the number had grown to 200. The

zones have appeared off Chesapeake Bay; the Oregon coast; the Kattegat Strait between Sweden and Norway; the Baltic Sea, the largest at 39,063 square miles (100,000 km<sup>2</sup>); and the northern Adriatic Sea. New dead zones are developing in the Archipelago Sea, Finland; Mersey Estuary, United Kingdom; Elefsis Bay, Greece; Mondego River, Portugal; coastal waters of South America (Paracas Bay, Peru, and Montevideo Bay, Uruguay); China (Pearl River estuary and Changjiang River); Japan; Southeastern Australia; and New Zealand, among many others.

### CAUSES OF DEAD ZONES

The primary cause of the larger dead zones is the overuse of agricultural fertilizers, but there are many sources. There are even natural sources such as inland flooding, which can cause freshwater to cover a large enough area of salt water to interfere with oxygen exchange. Heavy erosion of soils can add natural nutrients to rivers, and there is evidence of ancient dead zones that predated human colonization in many areas including the Gulf of Mexico. The recent increases in dead zones, however, are all anthropogenic. Increased demand for food leads to increased usage of fertilizers and increases in animal waste, which also cause problems. Automobile exhaust and some smokestack emissions contain significant amounts of nitrogen, which contribute significantly to air pollution fallout. Probably the most significant cause of the rapid increase in new zones in the United States and other areas is the boom in coastal building. Excessive use of fertilizers in lawn care winds up in storm drains and empties into estuaries and directly into oceans. Septic tanks may leak and further contribute to nutrient increases. The heavy development is especially prevalent on the east coast of the United States, which will wind up peppered with dead zones under the current trend. Considering that warm water enhances the phytoplankton blooms, global warming may also be contributing to the development of dead zones.

### ECOLOGY OF DEAD ZONES

The ecology of dead zones is complex. As oxygen levels drop, species respond differently. Once the oxygen levels fall below 5 ppm, fish and many other marine animals have difficulty with respiration. Once levels reach 3 ppm, sharks begin vacating the affected area, whereas most other fish remain until the level is 2 ppm. Marine organisms that cannot escape the area begin dying at 1.5 ppm, and most are dead by the time the typical 0.5-ppm levels are attained. Not all marine organisms, however, are negatively affected. Comb jellyfish, among a few

Map of the world showing the location of dead zones

other species such as stinging sea nettles, can survive in hypoxic conditions and, because of the lack of competition, can actually thrive. These, however, are not desirable species as they consume vast quantities of Zooplankton and eggs and larvae of fish and vertebrates that would otherwise support more ecologically useful species. Atlantic croakers can withstand hypoxia better than most species. They patrol the edges of the dead zones and poach the fleeing, weakened fish as they try to escape. They flourish as a result. Even shrimp trawlers watch for the edges of the dead zones because they tend to be rimmed with fish trying to resist being pushed away from their ancestral spawning/feeding grounds. They have record catches from these areas.

There is very little good news with regard to dead zones. Two bright spots are in the largest dead zones in the Black Sea and the Baltic Sea. The collapse of the Soviet Union, in 1989, ended the centrally planned economies in Eastern and Central Europe. The extensive agricultural activities were strongly curtailed, and fertilizers became too costly to use in excess. Between 1991 and 2001, the Black Sea dead zone, which had been the biggest in the world, largely disappeared. The Baltic Sea dead zone is still the largest in the world and a permanent fixture. Oxygen levels have slowly risen in the zone, and some species are even returning after many years

of absence. The collapse of the Soviet Union is part of the reason; another is that countries along the Rhine River have initiated policies that have limited nitrogen input. As a result, the North Sea dead zone shrank by 37 percent between 1985 and 2000.

## Gulf of Mexico Dead Zone

There is an area just south of the mouth of the Mississippi River in the Gulf of Mexico that annually develops conditions of hypoxia. The zone appears in February and grows continuously into the summer, when it peaks in size before dissipating in the fall as large storms sweep in. The average size of the zone is 5,000 square miles (13,000 km<sup>2</sup>), but, in 1999, it grew to 7,700 square miles (20,000 km<sup>2</sup>), or roughly the size of New Jersey, and it was even larger in 2001. This area has been called a dead zone because the oxygen levels drop so low (<2 mg/L) that fixed or slow-moving marine life such as crabs, clams, snails, worms, and echinoids slowly suffocate. The quick-swimming animals abandon the area at the first sign of trouble. Thus there are very few, if any, living animals in the zone of hypoxia.

The Gulf of Mexico dead zone is caused by the influx of huge amounts of nitrogen as nitrate primarily from the Mississippi River. The river delivers 140

cubic miles (580 km<sup>3</sup>) of freshwater drained from 31 states and more than 41 percent of the continental United States. Half of the nation's farmlands drain into this freshwater either through tributaries or directly into the river. The amount of fertilizer used on these farms has increased dramatically since the 1950s. The amount of nitrate from fertilizer delivered into the Gulf of Mexico from the river tripled between 1960 and 1997, and the amount of phosphates, another fertilizer, doubled during the same period. More than 1.75 million tons (1.6 million metric tons) of nitrate per year was being introduced through the river by the late 1990s, 30 percent of which is estimated to originate from agricultural fertilizers, 30 percent from natural soil decomposition, and 40 percent from several sources including animal waste, sewage treatment plants, and air pollution fallout from industrial and transportation sources.

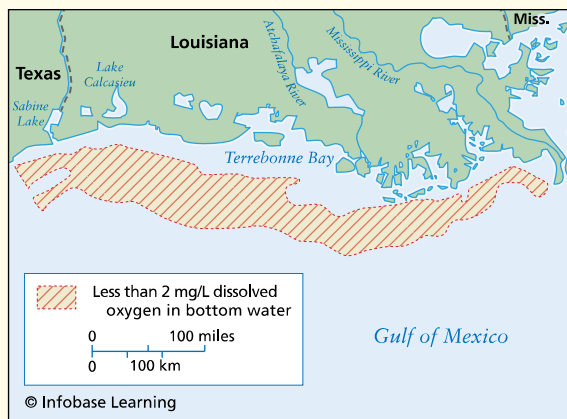

Diagram showing the steps in the eutrophication of the Gulf of Mexico at the mouth of the Mississippi River and the subsequent development of a "dead zone" as the result of excess input of fertilizer

**Deepwater Horizon oil spill U.S. Gulf of Mexico (April 20, 2010, to September 19, 2010) Water Pollution** Two days before Earth Day, on April 20, 2010, a semisubmersible drilling rig, the *Deepwater Horizon*, experienced an uncontrolled, catastrophic release of pressure known as a blowout during drilling operations about 40 miles (64 km) south of the coast of Louisiana in the Gulf of Mexico. The explosion and massive fire that followed killed 11 people, injured 17, and caused the worst off-

shore oil spill in U.S. history. The drill rig was under lease to BP (British Petroleum) and was owned and operated by Transocean, Ltd. one of the largest oil-drilling companies in the world. Over the next three months, up to 2.5 million gallons (9.5 million L) of oil were released daily into the Gulf of Mexico. This blowout became the most severe environmental crisis to occur in a U.S. territory. The *Deepwater Horizon* disaster, however, was not the first such disaster in the petroleum-rich Gulf of Mexico.

**Map of the hypoxic dead zone in the Gulf of Mexico at the mouth of the Mississippi River shown by the shaded area**

When the nitrates (and phosphates) enter the Gulf of Mexico, they act as nutrients for algae, whose populations grow rapidly in a “bloom.” A complex sequence of events then ensues in which organisms that feed on the algae also grow rapidly and produce huge amounts of waste. All of the waste triggers the rapid growth of bacteria that feed on the waste from both the algae and consuming organisms and, in the process, use up all of the dissolved oxygen in the water. The hypoxic zone grows from deeper levels to near the surface as it develops. The water undergoes eutrophication, which results in the death or driving off of all life in the affected zone. The zone grows larger as more nutrients are added to the water as long as there are no storms or other events that can disrupt the system.

The dead zone was first recognized in the Gulf of Mexico in the 1970s, but the location could not be accurately mapped until the 1990s. The problem is that it moves around from year to year and changes sizes and shapes. It has now been mapped fairly accurately for the past 21 years. It is controlled by a number of factors including the amount of fertilizer used in the midwestern farmlands, the extent of precipitation and

runoff in the farmland relative to precipitation in other areas of the Mississippi drainage basin, water temperature in the gulf, and the number of hurricanes and other storms in the gulf. The ideal situation is heavy fertilizer usage and precipitation in the farming areas along the Mississippi and drought throughout the rest of the basin and a calm, warm Gulf of Mexico.

The dead zone is devastating to the fishing industry in the gulf and even results in unexpected consequences such as an increase in shark attacks along the coast because of the lack of food for them. For that reason, an agreement was reached and law passed on October 11, 2000, to allocate \$1 billion per year until 2015 to reduce the amount of nitrogen in the Mississippi River by 30 percent. It is not an easy task because population growth adds nitrogen directly to runoff by increasing residential areas and automobiles and indirectly by placing higher demand on agricultural areas for more food.

### GULF OF MEXICO PETROLEUM

In Late Triassic period, some 230 million years ago, the breakup of the global supercontinent Pangaea was well under way. The North American plate had started to move (rift) away from the African and South American plates. The new ocean crust created in the gaps between these plates formed a low-lying geologic basin, or depression, by the Middle Jurassic (170 million years ago) that today makes up the Gulf of Mexico. The continental landmasses of North America,

Mexico, the island of Cuba, and parts of the Caribbean surround and define the Gulf of Mexico basin.

After its formation, the Gulf of Mexico entered a long period of geologic quiescence. During this time and continuing today, the freshwater of more than 150 major rivers that drained almost 1.5 million square miles (3.9 million km<sup>2</sup>) of North America empty every year into the 600,000 square miles (1.6 million km<sup>2</sup>) of the Gulf of Mexico basin. These 280 trillion gallons (1,060 trillion L) of freshwater

carry clay, silt, sand, and gravel, as well as dissolved ions of potassium, calcium, and sodium. The gentle waves and small tidal fluctuations allowed most of this sediment to deposit rather than be washed away, as it does in larger ocean basins. Eventually, a ring of sediments deposited around most of the outer edge of the basin, forming a wide, gentle mantle of unconsolidated silt, sand, and gravel deposits on the continental slope. Farther seaward, a blanket of sediment more than nine miles (14.5 km) thick created and then buried subbasins, channels, and valleys. These features formed as sea level fluctuated in response to plate tectonic movements, glaciations, and local climatic changes.

The carbon-rich organic matter from the remains of plants and animals were also carried with the sediments by the rivers. As the continual in-pouring of sediments compressed the organic material, it was heated, pressurized, and eventually converted into oil and gas through a complex series of chemical reactions and accumulated in geologic features known as oil and gas “traps” deep beneath the seafloor.

**The *Deepwater Horizon* on fire after a catastrophic failure of its blow-out preventor and related safety systems (U.S. Coast Guard photo/Released)**

## GULF OF MEXICO RESOURCES

Petroleum geologists estimate that there are 4,300 billion barrels (684 trillion L) of recoverable petroleum and 170,000 billion cubic yards (130,000 billion m<sup>3</sup>) of usable natural gas beneath the seafloor of the Gulf of Mexico. Current offshore exploration and production operations employ 60,000 workers and produce about 25 percent of U.S. natural gas and almost 13 percent of domestic oil. Mexico reports oil production from the gulf in the range of 2.7 million barrels (430 million L) and more than 52 million cubic yards (40 million m<sup>3</sup>) of natural gas. Oil production and exploration companies have drilled about 4,000 oil and gas extraction wells in the Gulf of Mexico.

Behind oil and gas, tourism (recreational bathing and sports fishing) is the second-largest industry in the Gulf of Mexico, with an annual value of more than \$100 million. Every year, tens of thousands of people visit the sandy beaches to enjoy the warm, gentle waters of the Gulf Coast. Almost 20 percent of the nation's seafood comes from the Gulf of Mexico, where commercial fishermen harvest 2 billion pounds (0.9 billion kg) of fish and shellfish annually. This \$1-billion-a-year industry represents a significant portion of the economies of the five Gulf Coast states: Texas, Louisiana, Alabama, Florida, and Mississippi. The 3,500 miles (5,633 km) of inland bays, shorelines, estuaries, and wetlands also host thriving ecosystems for migratory birds as well as for thousands of indigenous plants and marine mammals and upland animals.

## DRILLING THE MACONDO PROSPECT

In early spring 2010, oceangoing tugs moved a relatively new offshore drilling rig, the *Deepwater Horizon*, into position. The *Deepwater Horizon* was to drill an exploratory oil well into a promising area within a portion of the Mississippi Canyon, a submerged, steep-side valley on the seafloor of the Gulf coast's continental slope. In 2008, BP, formerly British Petroleum and one of the largest energy companies in the world, purchased the right to drill for oil in the area from the U.S. Minerals Management Service, or MMS. BP code-named the Macondo prospect from a fictional town described in Gabriel García Márquez's Nobel Prize-winning novel *One Hundred Years of Solitude*. The MMS was the government agency that, until recently, was responsible for promotion, oversight, and regulation of offshore mineral resources, including oil and gas exploration and development. BP estimated that the Macondo prospect or reservoir might hold 50 million barrels (8 billion L) of recoverable oil, in addition to

significant amounts of natural gas. Geologists have calculated that the reservoir is some 13,000 feet (4 km) below the sea floor and at one mile (1.6 km) water depth.

Once the *Deepwater Horizon* was in position, operators partially flooded the pontoons upon which the drilling platform floated. This brought the rig to an appropriate operational height and provided the ballast needed to maintain a stable working platform. A computer-controlled set of propellers and thrusters would keep the rig centered over its borehole as powerful drill bits cut through seafloor sediment and rock in search of oil and natural gas. The rig positioning system, called dynamic propulsion, turned thrusters on and off based on input from special sensors that could read wind speed, direction of current, and other factors affecting the position of the drilling platform. Constructed in 2001, the *Deepwater Horizon* was designed to operate in up to 8,000 feet (2.4 km) of water and drill up to 30,000 feet (9.1 km) into the sea floor.

The Gulf of Mexico has an average water depth of approximately 5,300 feet (1,615 m). Oceanographers postulate that in its deepest portions, called abyssal areas, water depths are 12,500 to 14,100 feet (3,800 to 4,300 m). Operating a drilling platform almost a mile above the seafloor is complicated. The thick-walled steel pipes and powerful bits, clamps, and tools that are strong on the surface can behave as if soft and plastic when lowered deep below the surface where water pressures are in excess of 300,000 pounds per square foot (1.46 million kg/m<sup>2</sup>).

Although the specific procedures used on the *Deepwater Horizon* are not yet widely available, it is likely that Transocean, Ltd., installed the well in a manner similar to that described below.

When a deepwater (depths greater than 1,000 feet [305 m]) offshore well is drilled, steel pipe or tubing, called casing, is lowered to the seafloor and pushed or hammered several hundred feet into the loose sediment. This process, called “spudding in,” provides the main structural support for the installation of the drill pipe. The casing is usually 36 inches (0.9 m) in diameter but can be as wide as 72 inches (1.8 m) depending on the depth of the well and sediments through which it is drilled. In the Gulf of Mexico, overlying sediment is so unconsolidated that casing often can be “washed” into place by using powerful jets attached to the end of the steel pipes. Once platform crews (sometimes referred to as roughnecks) install the casing, the next step is to assemble the drill string of 30- to 45-foot- (9.1- to 13.7-m) long sections of six-inch (15.2-cm) diameter steel pipe connected together to the desired length and attached to a diamond-tipped drill bit at the

end. The operator lowers the drill string from the platform and threads it like a needle into the top of the wellhead a mile below the water’s surface. Platform crews sometimes accomplish this with the aid of remotely operated submersible vessels.

The driller rotates the string by engaging a powerful engine through hydraulic gears attached to a drive mechanism (called a turntable) on the platform and adds sections of drill pipe as needed to advance the well. The bit at the end of the string cuts through the sediment and begins to extend the borehole below the seafloor. During drilling, platform personnel pump a specially formulated mixture of water, barium, and clay, called drilling fluid or mud, through the center of the drill pipes into the borehole. Drilling mud keeps the drill bit cool and flushes particles of displaced sediment, called cuttings, to the top of the wellhead.

The most critical reason platform operators use mud is to manage the pressures encountered during drilling. Forcing a narrow-diameter pipe deep into the ground is similar to coring through the cork of a champagne bottle. The oil and gas are under tremendous pressure, and if encountered unexpectedly they quickly expand and rise up through the borehole, driving the drill string, casing, and everything else in their path toward the surface. Drillers call this a “kick” and balance the pressures by forcing more and heavier drilling mud into the borehole.

As the borehole is deepened, usually between 1,000 feet to 2,000 feet (305 m to 610 m) into the seafloor, the drill string is withdrawn and the platform operators thread another length of casing, 22 inches (55.9 cm) in diameter, through the 36-inch- (0.9-m) diameter casing and join the two together using special fittings. One of the most critical parts of the operation is the grouting in place of the “22” using high-pressure, quick-setting concrete. A mistake in grouting renders the structural stability of the well suspect and is very expensive and difficult to correct.

Once “22” grouting is completed, operators attach the blowout preventor (BOP) and marine riser to the top of the wellhead casing on the ocean floor. The BOP can be up to five stories tall and weigh upward of 400 tons (363 metric tons). It is a sophisticated set of control or cutoff valves, with numerous backup systems that shut if a “kick” occurs, stopping the high-pressure escape of oil and gas from the well. This prevents the uncontrolled release of fluids (oil) or natural gas and allows the driller to counterbalance the expected or unexpected rise in pressure by pumping heavier drilling mud into the borehole. If a kick occurs, the force exerted on the well casing is severe and therefore requires that the

grout secure it firmly in place. A blowout occurs if the BOP fails and oil and gas gush from the well in an uncontrolled manner. Blowouts, which can result in the accumulation of highly flammable and explosive concentrations of oil and natural gas on and underneath the drilling platform, are extremely dangerous and have been responsible for the deaths of many oilfield and offshore platform workers (see *PIPER ALPHA OIL SPILL*). Installing and testing BOPs are some of the most important components of a drilling platform's safety program.

Connecting the top of the subsea wellhead and the BOP to the drilling platform is a sequence of hollow steel pipes called the marine riser. It is through this that platform operators lower the drill bit, drill string, and mud into the borehole. The marine riser also allows for the removal and collection of cuttings. As platform operators advance the borehole deeper into the subsurface, mud and cuttings are washed up through the center of the drill bit between the drill string and casing and through the marine riser to the drilling platform. Roughnecks collect the mud/cuttings mixture in special separation tanks. The mud, which is expensive, is recycled and the cuttings are stored for logging and study before they are disposed of onshore. Completion of the borehole and construction of the well to the pay zone—the depth at which geologists expect to encounter oil or natural gas—is done by placing and cementing additional lengths of progressively narrower casing as dictated by the different strata and pressures. Costs for completing an oil well in deep water are in the range of \$100 million up to \$250 million for wells as deep as six miles (10 km).

### **THE DEEPWATER HORIZON BLOWOUT**

On April 20, 2010, the Macondo prospect well (designated MC252 by BP) was near completion, at 18,000 feet (5.5 km) below the seafloor, with cementing of casing finished and planning under way for the installation of a production pipe, a device to collect the oil and natural gas and bring it to the surface. Drilling was five weeks behind schedule, and BP would soon have to start paying \$500,000 a day in extended lease charges. Halliburton, a large multinational oil-service company, was in charge of cementing (grouting) operations.

As 9:45 CDT, the BOP failed catastrophically, and a cloud of methane rushed out of the well, enveloping the rig. Eleven minutes later, the platform burst into flames. The 126 crew members followed their training and abandoned the rig using lifeboats to motor to a nearby service vessel. Helicopters transferred 17 injured survivors to onshore

hospitals and trauma centers. Despite a three-day search, the U.S. Coast Guard was unable to find 11 missing crew members, now presumed dead. They are thought to have been close to the top of the well when the explosion and fire occurred.

The *Deepwater Horizon* burned for almost 40 hours before sinking. At the time of the explosion and fire, BP and Transocean executives were touring the rig to discuss plans for production well operations and to present a safety award for seven years of operation without a lost-time accident. They were not among the injured. There were some reports (vehemently denied by Transocean) that survivors were held incommunicado at sea or in a Louisiana hotel until they could be debriefed by company safety and security specialists.

As is typical in these types of environmental disasters, the responsible parties (primarily BP) at first sought to downplay the potential for major ecological damage from the blowout. Initial statements by BP reassured the press and Coast Guard that very little to no oil was leaking from the damaged wellhead. Based upon data provided by BP, 24 hours later the Coast Guard calculated the flow rate from the uncapped well at approximately 1,000 barrels (159,000 L) per day. This number proved to be a woeful underestimate, and by early July independent experts and government scientists estimated that between 1 million to 2.5 million barrels (159 million to 398 million L) of oil were being discharged from the well every day.

Although numerous investigations are under way, including those sponsored by the federal government, BP, BP's insurers, Transocean, and others, it is clear that a blowout occurred and that the BOP, and its redundant backup systems, failed. The reason for the failure has yet to be determined, but preliminary findings suggest that the BOP may have been damaged during drilling operations.

The response by BP and the government to the disaster began slowly and was disorganized. As oil flowed into the gulf, coastal communities began to complain about a lack of response or preparation from BP and the Coast Guard. Deployment of booms to contain the spread of the spill was delayed, and skimming operations were spotty and ineffective. It took several weeks before the Coast Guard, with help from BP, established a workable, unified response organization. BP stated on more than one occasion that it would take financial responsibility for the cleanup and, after pressure from the White House, set up a \$20-billion compensation fund to pay for the economic consequences of the blowout.

Under the direction and oversight of the Coast Guard, BP developed and implemented a multifac-

eted, creative, and comprehensive approach (subsea, surface water, and shoreline) to the *Deepwater Horizon* disaster. Subsea efforts include:

### Top Kill Procedure

BP attempted to plug MC252 by pumping in a mixture of heavy drilling mud and bridging material (pieces of rubber, golf balls, short segments of rope) through the damaged BOP (which was still attached to the top of the casing) and into the well. Although often successful in shallow water blowouts, this was the first time this procedure was attempted in a deepwater blowout. The effort failed after several attempts and was abandoned by BP and the Coast Guard over concerns that further efforts could exacerbate the damage to the BOP.

### Subsea Containment Structure

BP lowered a 125-ton (113-metric ton), 340 square-foot (31.6-m<sup>2</sup>) dome-shaped vessel (Top Hat) over the top of the well to capture flowing oil and divert it through a riser pipe to surface ships for shipment to shore. However, gas hydrates, crystals of methane similar to ice crystals, formed inside the Top Hat and blocked the flow of oil. BP removed and deposited the Top Hat on the seafloor and evaluated other options.

### Riser Insertion Tube

After the blowout and sinking of the *Deepwater Horizon*, the marine riser pipe, still attached to the BOP, folded over like a bent straw. Oil poured through the end of the now crumpled riser that lay on the floor of the gulf under a mile of water. One of BP's earliest attempts to control the flow of oil was to insert a tube into the end of the marine riser and divert oil to surface vessels. This approach had limited success in capturing oil, but it did collect some oil and gave BP the opportunity to try other containment strategies.

### Lower Marine Riser Package Cap

This containment system was installed after BP removed the damaged marine riser pipe from the top of the BOP. Once remotely operated submersibles sheared off the damaged riser pipe, operators lowered a second pipe onto the BOP and sealed it in place. Using a truly creative engineering solution, BP engineers installed feed lines into the Riser Package Cap to prevent the formation of hydrates. The Riser Package Cap collected and carried oil and natural gas to two surface vessels for processing. This was a major step forward in collecting the oil that allowed BP to continue to explore options to improve the efficiency of oil collection and stop the flow of oil.

### Capping Stack

BP's engineers designed and installed a three-valve, or ram, cap on top of the BOP. The idea behind this device was to close each valve and slowly cut off the flow of oil and seal the well. Under scrutiny of the U.S. Coast Guard, remotely operated submersibles gently lowered the capping stack into position. Once in place, technicians began to close each valve, monitoring pressure readings to ensure that well integrity was not compromised and to prevent another blowout. After 48 hours of continuous monitoring and testing, BP concluded on July 17, 2010, and the Coast Guard agreed, that the cap had worked and no oil was leaking into the gulf from MC252. This was the first time such a system had been deployed successfully at these depths. BP then pumped cement grout into the well, called the static kill, and declared the well shut in, or not discharging any more oil, on July 17. The Coast Guard declared the *Deepwater Horizon* blowout officially under control when BP placed the relief well into service.

### Drilling of Two Relief Wells

Contractors for BP drilled two new oil wells into the Macondo Prospect near the damaged MC252 well—to pump a mixture of cement and grout through the well casing and annular space and finally seal it. Relief well DD3 came within 3.5 feet (1.1 m) horizontally and 50 feet (15.2 m) vertically of MC252 when drilling was halted in order to pressure test the casing and grouting of MC252. Once completed, the relief well was used to reduce the pressure within the same geologic strata in which the *Deepwater Horizon* well was finished and to bottom kill the well. This procedure was completed on September 19, 2010, and the *Deepwater Horizon* well MC252 was declared plugged and abandoned.

BP also attempted to contain the distribution of the oil from MC252 once it entered the surface water system. Techniques used included dispersants, skimming, and *in situ* burning.

### Dispersants

Under the direction of the Coast Guard and with the help of the U.S. Air Force, BP deployed hundreds of thousands of gallons of dispersants into Gulf Coast waters. These chemicals, released from specially designed aircraft, broke the oil into small droplets that dissolved in the seawater and became bioavailable for naturally occurring bacteria and other microorganisms. Dispersants had to be carefully monitored and controlled because, if overused or applied improperly, they can have serious ecological consequences (see *TORREY CANYON OIL SPILL*).

### Open Water Skimming

BP deployed almost 300 commercial skimmers. These specially designed vessels corral and concentrate oil by using floating booms. Once enclosed, oil-skimming pumps remove the tar-like oil into holding tanks for later disposal or reprocessing. For skimmers to be effective, water surfaces must be calm and wind speeds low. BP estimated that it collected approximately 30 million gallons (114 million L) of oil-water mixture, with oil making up about 10 to 20 percent.

### In Situ Burning

In some cases, after skimmer ships collected the oil behind fire-resistant booms, it was set on fire. In order for combustion to be sustained, oil had to be the correct thickness, usually more than one inch (2.54 cm). BP only conducted in situ burning after it received permission from the appropriate regulatory agencies, which monitor weather conditions to ensure that public health and safety is not at risk. Regulatory officials estimate that about 10 million gallons (38 million L) of oil were destroyed via in situ burning.

Despite these and other oil collection and control measures, liquid hydrocarbon from MC252 reached shorelines and fouled beaches in Louisiana, Mississippi, Alabama, and Florida. BP's shoreline protection strategy included the use of booms and onshore cleanup teams.

### Booms

These nonabsorbent, closed-cell polyethylene plastic tubes are designed to float on the surface to prevent oil from washing up on the shoreline. Skimmer ships must patrol regularly in front of the boom to remove oil and other debris that collect against them. Booms typically have about six inches (15.2 cm) of freeboard (area above the surface) to reduce splash over and about 12 inches (30.5 cm) of draft or curtain (area below the surface) to divert underflow. Booms come in varying lengths and are joined by quick-connecting lengths of galvanized chain or rope. Using emergency response contractors and local ships with special health and safety training in its Vessels of Opportunity program, BP deployed hundreds of thousands of feet of booms along the Gulf Coast shoreline. The booms had varying degrees of effectiveness, depending upon weather and wave conditions. Many local communities complained that BP was slow to deploy the booms, despite repeated, often frantic, requests.

### Onshore Cleanup Teams

BP hired and trained more than 15,000 workers to remove oil from Gulf Coast beaches. These workers

used shovels and heavy equipment (front-end loaders and graders) to collect and remove oil-contaminated sand for processing and disposal. Depending on the extent of beach oiling, they constructed sand berms to prevent the further onshore flow of oil, or they collected by hand individual "tar balls" that washed ashore. This last line of shoreline defense was less effective in recovering oil from the thousands of isolated bayous, inlets, and channels that dot the Gulf Coast and serve as habitat for large numbers of birds, mammals, and reptiles.

### MEDIA COVERAGE

Although catastrophic, the *Deepwater Horizon* blowout is not unique. In early June 1979, near the Bay of Campeche, Mexico, a catastrophic blowout occurred at the oil production well *Ixtoc I*. Over the next 10 months, an estimated 140 million gallons (530 million L) of oil leaked into the Gulf of Mexico. Thirty years later, beachcombers and divers still can find asphaltic residues from that spill on beaches and reefs along the Mexican and U.S. coastlines. Ten years earlier, an oil well blowout near Santa Barbara formed an 800-mile (1,288-km)-long slick and killed more than 4,000 seabirds.

The *Deepwater Horizon* blowout is the most well-publicized environmental disaster of all time. Advances in technology and the presence of the Internet allowed the viewing of oil spewing out of the well and the remotely operated submersibles working a mile (1.6 km) deep through the "oil cam," a series of underwater cameras. This high level of visibility greatly increased pressure on elected officials and BP to mobilize needed spill-response resources. During the 85 days before BP was able to cap MC252, President Obama visited the Gulf Coast four times, responding to claims that his administration was not acting quickly enough and reassuring residents that the federal government was engaged proactively in cleanup efforts.

BP and federal agency officials did not place restrictions on media coverage, except as it related to the safety and privacy of response workers and the effectiveness of oil-recovery activities. Correspondents were able to roam beaches and observe how the cleanup progressed, film skimming and controlled burning operations from charter boats, and freely question BP and government representatives during regular press briefings. There were several incidents of BP security personnel and local police briefly detaining, questioning, and allegedly attempting to intimidate reporters, but these seemed to be infrequent, isolated occurrences. BP also undertook a very polished public relations campaign, using radio,

television, the Web, and print ads to publicize its efforts to clean up the spill and rehabilitate its image.

### ECOLOGICAL DAMAGE

The failure of the BOP at MC252 has been compared to the release of 11 million gallons (41.6 million L) of oil from the *Exxon Valdez*. However, researchers and scientists must use caution in attempting to rely on the ecological damage caused by the *Exxon Valdez* spill as a benchmark for effects that may be related to the *Deepwater Horizon* blowout. There are more differences between the two spills than there are similarities.

Prince William Sound, where the *Exxon Valdez* disaster took place, was relatively ecologically pristine compared to the Gulf of Mexico, which has a number of well-documented, modern-day pollution problems (see DEAD ZONES, for example). The ecosystem of the Gulf of Mexico is commonly exposed to oil, with natural seepage from subsurface geologic formations alone possibly releasing up to 165,300 tons (150,000 metric tons) annually. Native Americans living along the Gulf Coast used oily tars produced by this seepage in pottery and waterproofing since prehistoric times. Although natural oil seepage may have allowed for some adaptations by Gulf Coast organisms, these would be overwhelmed by the amount and speed of the MC252 release.

The ratio of the volume of oil released by the *Exxon Valdez* into the water in Prince William Sound was much higher than in the *Deepwater Horizon* spill. The *Exxon Valdez* spilled fresh, highly toxic oil directly on ecologically sensitive areas, whereas the *Deepwater Horizon* leaked oil in the open ocean, where it degraded to a much less toxic form before reaching the coast. The movement of oil within the sound, which is only 45 miles (72.4 km) wide, was more restricted than in the larger gulf, and as a result it did not spread as far. Climate also played a key factor in how the Alaskan ecosystem responded to the oil. With short summers and very severe winters, oil movement and degradation is slower. The oil from the *Exxon Valdez* had an extended residence time within the environment that likely magnified its impact, whereas Gulf Coast waters and air temperatures are warmer and more quickly degraded and dispersed the oil.

Despite these and other differences, scientists and policy makers used ecological effects from the *Exxon Valdez* as a rough set of precursors for the ecological damage likely to occur because of the *Deepwater Horizon* event. MC252 blew out at the beginning of the gulf's peak spawning and nesting

season for numerous varieties of fish, birds, and sea mammals. At particular risk are the brown pelicans, Ridley and loggerhead sea turtles, whales, and coral reefs. Effects to these creatures will be severe for many years to come. Higher-level organisms that rely on shrimp and crustaceans, which form the base of the Gulf Coast food web, either will die off or be forced to abandon Gulf Coast waters for new hunting and foraging areas. Neither the government nor BP has published an estimate of animal fatalities, but using the Prince William Sound effects as a guide, they likely will be in the many thousands. Within weeks of the release, volunteer animal rescue groups were reporting hundreds of sick and dead birds and marine mammals and fish washing up on beaches and floating in coves and bays.

Fisheries will take several years to recover and, as is claimed by many local fishermen at Prince William Sound, may never return to pre-spill numbers. Vegetation along the coastline will fare better. Depending upon how heavily oiled, they are projected to return to their pre-spill levels within three to five years. The animals relying on that vegetation for food and habitat will be displaced or greatly distressed during this time. Despite the billions of dollars being spent on oil recovery, ecological damage in the gulf will be extensive and long-lasting.

One important factor that researchers take into account in assessing long-term ecological effects from MC252 is the presence of a dissolved layer of hydrocarbons detected below the water's surface within the gulf. Although oil is less dense than water and does not readily mix with it, this usual chemistry is only applicable within a narrow range of pressure and temperature. The millions of gallons of oil, much of it containing high concentrations of dissolved methane, 5,000 feet (1.5 km) below the surface interact differently with seawater than does oil at the surface. Scientists measured a 30-mile (48-km)-long lens of dissolved oil seven miles (11 km) wide and hundreds of feet thick near MC252. No one is sure how long this lens will remain intact and what the ecological implications of its presence are. One result is that the carbon in the oil may serve as a nutrient source for the growth of microorganisms that consume dissolved oxygen in the seawater. Indeed, lower oxygen levels were found in the area of the plume. Eventually, this could create a large "dead zone," similar to that farther north at the mouth of the Mississippi River. The widespread use of dispersants that chemically encourage oil to dissolve and mix with seawater could compound this effect.

Unlike the Mexican government response after the *Ixtoc I* blowout in 1979, BP has created a substantial

research fund to study and quantify the ecological effects the MC252 spill has had and will have on Gulf Coast ecosystems. These studies, combined with long-term government-run monitoring programs, will form the basis for a restoration plan that will support and enhance nature's own recovery efforts within this critically important water resource and habitat.

### REASONS FOR THE BLOWOUT

It will be years before engineers and safety experts are able to assemble a definitive explanation of the events onboard the *Deepwater Horizon* that led up to the blowout. However, the causes probably will be directly or indirectly related to several factors.

1. One of the most egregious reasons for the blowout is the failure of federal regulatory agencies, particularly the now-defunct Minerals Management Service (MMS), to provide consistent and effective oversight and enforcement of the permits it issued to the operators of the *Deepwater Horizon* as well as the MMS's own deep-water drilling regulations. Congressional hearings shortly after the blowout strongly emphasized this failure and ridiculed MMS-approved spill-response plans of companies for including procedures to protect walrus, which do not inhabit the Gulf of Mexico, and containing emergency contact information for a scientist who had died several years ago. MMS appears to have become a "rubber-stamp" for oil company drilling operations in the Gulf of Mexico.
2. Complementing the regulatory failure was BP's inability or unwillingness to insist that its subcontractors and vendors hold paramount the health and safety of its workers and the protection of the environment. This obligation, which BP espouses as one of its core corporate values, apparently was not part of the *Deepwater Horizon*'s operational culture. Early, unconfirmed post-blowout reports have described several events when BP executives placed significant pressure on *Deepwater Horizon* staff to continue to drill, even as roughnecks and platform engineers began to express serious concerns about the functional capability of the BOP and stability of the borehole. These accounts take on added credibility considering the 2005 industrial accident at a BP refinery in Texas City, where an explosion killed 15 workers, all subcontractors, and was caused by a faulty and poorly operated venting system. The Occupational Health and Safety Administration, OSHA,
3. Transocean, the operator of the *Deepwater Horizon*, is also held accountable for the blowout. Their adherence to safety appears to have been relaxed when BP, a major customer, applied contractual pressure. Unconfirmed post-blowout reports by Transocean staff described a pattern of behavior by senior Transocean managers of discounting safety concerns if they interfered with drilling or well-completion operations. News reports quoted surviving Transocean employees describing a company culture where safety was important but not important enough to threaten the bottom line.

The causes of the *Deepwater Horizon* blowout will be studied, litigated, and debated for years, but this process will not last as long as the ecological and economic damage caused by releasing more than 204 million gallons (772 million L) of oil into the Gulf of Mexico—the worst environmental disaster in U.S. history.

**delta** A delta is the feature that is produced where a river enters a low-lying area called a receiving basin, be it the ocean, a lake, or any other standing body of water. A delta is formed when a river or stream has a generally unidirectional flow that is strong enough to carry sediment and enters a body of water that has no flow or whose flow is contrary to the river. The slowing to stoppage of flow causes the carried sediment to deposit at the mouth of the river. Depending upon the volume of sediment and the flow rate of the water being discharged into the receiving basin, different delta shapes or geometries are possible: bird's-foot, lobate, semicircular, or the classic  $\Delta$  with the tip pointing upstream. There is a general division between delta types as constructive or destructive; constructive deltas are those formed in a low-energy basin, and destructive deltas those formed in a high-energy basin. *Constructive* means that new land is formed as the result of the process, and *destructive* means that no new land is formed. Each type has different environmental issues, depending upon the processes that formed it. Most deltas share the problem of poor water quality in the river. Most cities situated along a river remove water upstream of the city and release wastewater downstream of the city. It is said that the water in the Mississippi River, for example, is used and reused six times before it arrives at New Orleans.

### BIRD'S-FOOT DELTA

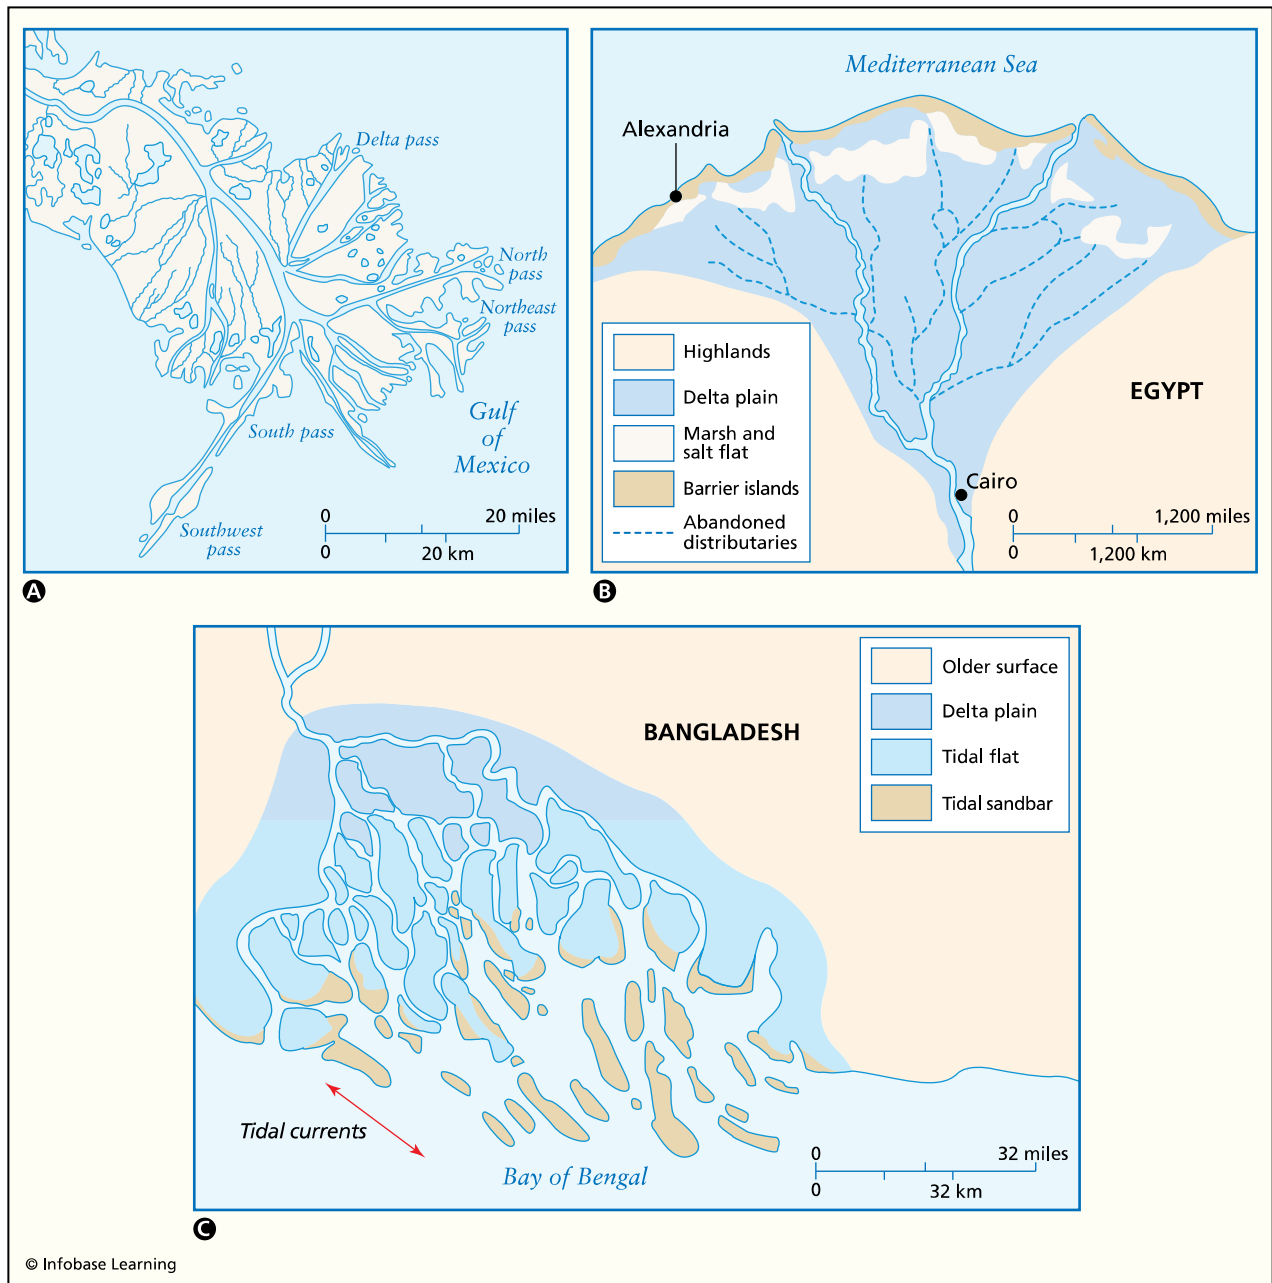

A bird's-foot delta is the most constructive type of delta. It requires extremely low-energy (small waves and tides) receiving basins to form. The best example of a bird's-foot delta is the Mississippi River delta in the Louisiana part of the very low-energy Gulf of Mexico. The low energy allows all deposits, both sand and mud, to be preserved. Bird's-foot deltas have a single main distributary channel, where virtually all of the activity takes place. Where the water from the river impacts the basin water, the flow slows abruptly but penetrates into the basin in a jet that may extend several hundred feet or more

past the end of the delta. This process causes massive amounts of sand to deposit right at the mouth in a distributary mouth bar, and progressively finer sediment deposits farther into the basin. With time, the channel cuts through the mouth bar, causing it constantly to shift basinward. This downstream movement of the mouth bar, called a progradation process, causes the mouth bar sand to be deposited over previously deposited (prodelta) silt, which is, in turn, deposited over prodelta marine clays. Therefore, the size of the sedimentary grains present in deltaic deposits becomes larger (coarsens up) closer to the present-day ground surface. As a result heavy sand is deposited over soft and weak clay, an unstable situation.

The growth of a bird's-foot delta involves the formation of levees composed of mouth bar sand covered by overbank deposits. Long thin strips of land containing the channel extend far into the receiving basin, stretching along the length of the river. The farther the river extends into the receiving basin, the more back pressure is exerted on the flow. At some point, commonly during flood conditions, this back pressure causes the river to break through levees at a weak or thin spot, and a splay forms. If the splay is small, it may just form a small delta off the main distributary channel. If the splay is large, the whole river may shift into this new channel, abandoning the old channel. Over time, this process of shifting channels spreads the delta out, creating a significant landmass. Where channels wrap around parts of the receiving basin, small bays form between the channels. These interdistributary bays may develop into lakes in some cases. The huge Lake Ponchartrain to the north of New Orleans was formed in this manner.

Environmental issues abound in bird's-foot deltas. The land is primarily composed of heavy sand resting on weak mud and silt, producing a gravitationally unstable situation. As soon as active sedimentation from the river shifts away from an area, the land immediately begins to sink into the underlying mud, and subsidence ensues. Hundreds to many thousands of acres of land may slowly sink below sea level and into the marine basin each year, depending upon the size of the delta. The constant shifting of the delta's distributary channel makes land management very complicated. Those deltas that form by rivers' emptying into the sea or ocean, such as the Gulf of Mexico, produce a constant threat of saltwater incursion. As the land subsides, salt water begins to mix and contaminate the freshwater from streams and rivers. The surrounding salt water also infiltrates the underlying groundwater system, making it nonpotable. In addition, lower ground

**Maps showing three types of deltas. Highly constructive “birds’-foot” delta of the Mississippi River as it enters the Gulf of Mexico in Louisiana (A); the classic constructive lobate Nile River delta in Egypt as it enters the Mediterranean Sea (B); the destructive tide-dominated Ganges-Brahmaputra River delta in Bangladesh as it enters the Bay of Bengal (C)**

elevations increase the risk of flooding and damage from coastal storms.

Typically on bird’s-foot deltas, the only source of freshwater is that supplied by its rivers and streams. This surface water system is very sensitive to spills and leaks from industrial operations and local waste treatment and disposal facilities. These spills and leaks can be rapidly distributed by the intertwining and connected nature of the delta’s surface water

system and compromise community water supplies throughout the delta.

The shifting nature of the streams and rivers operating within a bird’s-foot delta also make water supply planning difficult. If the river shifts, water supply intakes that once were fed by a stream or river suddenly run dry. There is no freshwater for the inhabitants downstream, and expensive public works projects must be designed and implemented

either to provide alternate water supplies or to reroute the stream or river that had been acting as the freshwater supply.

The discontinuous and episodic way sediments are deposited in a bird's-foot delta leads to large areas where there is only limited exchange of water between supply streams and the areas between channels. This results in the development of large zones of stagnant water in the vast swamps that are common to bird's-foot deltas. These can be breeding grounds for disease-carrying insects (vectors) and the source of illnesses such as malaria and typhus.

Finally, in tropical and semitropical regions because of the low elevation of bird's-foot deltas and their being surrounded by water, they can be more adversely impacted by coastal storms and hurricanes than higher-elevation, more geologically stable inland areas. The high winds and storm surge associated with Hurricane Katrina contributed to the failure of the levee system designed to protect New Orleans from flooding. It was these floods that devastated the city, killed hundreds, and resulted in the need for an expensive and massive rebuilding effort.

### LOBATE DELTA

Lobate deltas are also constructive but produce less new land than bird's-foot deltas. Lobate deltas were the source of the name *delta*, which was based upon the similarity of their shape to the Greek letter. The distributary channel enters the upstream apex of the delta and splits into a fan-shaped geometry of diverging (radiating) channels. One or more of these channels are active at any given time, and the active channels constantly shift back and forth across the delta. With sediment being continuously delivered to the receiving basin, the flat side of the delta against the basin grows into the basin, thus increasing the amount of land along a continuous front.

The reason that each active channel does not grow as in a bird's-foot delta is that the energy of the receiving basin of a lobate delta is higher than that of a bird's-foot delta. Wave energy is typically the reason. It spreads out the sediments across the front of the delta primarily through longshore currents. The classic lobate delta was the Nile River delta in Egypt. The building of the Aswan Dam, however, reduced the sediment supply enough to disrupt replenishment of the basin side of the delta, and it has been shrinking ever since. Under its strict definition, this would qualify it as a destructive delta.

The environmental concerns related to a lobate delta are generally similar to those of a bird's-foot delta. Saltwater incursion can be a problem, as can

pollution of the extensive surrounding wetlands. The lobate delta is typically very fertile and used extensively for agriculture. The release of fertilizers and pesticides into the river either from direct spraying or from runoff compromises the quality of the river water. Nitrates can cause increased biologic activity and low oxygen conditions, which result in fish kills and other problems. Irrigation and damming of the river can cause reduced sediment supply and the loss of land.

### TIDE-DOMINATED DELTA

In basins where tidal reach is high, rivers may become flooded, producing a distinctive tide-dominated delta within an estuary. The sand bodies are elongated in a tide-dominated delta and lie perpendicular to the coastline within the river mouth with a digitate appearance. High tide causes ocean water to be driven up the river up to several tens of miles. In the main river, the flow of the river reverses. This flow cuts tidal channels in the delta. During these conditions, the sand bodies are typically completely submerged. When the tide turns, water flows back down the river and through the channels. The sand bodies become land at this time. There are a distinctive group of sedimentary structures produced in these areas as a result of the reversing flow directions and submergence and emergence of the land.

False-color image of Mississippi Delta recorded by NASA's *Terra* satellite off the southern Gulf Coast in May 2001 (Image provided by USGS EROS Data Center Satellite Systems Branch as part of the *Earth as Art II* image series, NASA)

Environmental issues in tide-dominated deltas primarily involve saltwater incursion. The water in the whole lower portion of the river is typically brackish and nonpotable. Residents must obtain other sources of freshwater. The brackish water enters the groundwater system near the river, and pumping wells must be carefully monitored to prevent them from drawing it under heavy pumping or drought conditions. The interaction of freshwater and salt water can result in the formation of unexpected compounds. Certain species may be soluble in freshwater but precipitate if exposed to salt water. This is not a problem in natural systems, but if wastewater or other pollutants are added to the freshwater of the river, the chemistry of the system may be altered. The pollution may not be only from the freshwater source but also from salt water. Oil spills and waste disposed of at sea may return upstream to inhabited areas during rising tides. Tidal areas also tend to be swampy and may harbor disease, especially that which may be carried by mosquitoes.

### WAVE-DOMINATED DELTAS

For most rivers entering the sea, the wave energy far exceeds that of the river flow. The waves spread the sand and coarser material along the coastline in a beach and carry the fine material into deeper water. There is no real delta formed as in the other types, but instead the river empties into a beach, which represents the sand bodies. No new land is made, but the existing land is modified in its content of sand.

Environmental problems in a wave-dominated delta are similar to those at a beach. Waste washing up onshore, oil spills, and saltwater spray and incursion are some of the more common problems. The fragile ecosystem of a beach and lack of buffered transition zone between marine and nonmarine conditions make these areas particularly prone to problems caused by pollution and building.

**desertification** The original definition of desertification was the spread of existing deserts into surrounding productive areas. Since then, the term has evolved into a more general conversion of any productive area into desert conditions. Certainly, desertification can be a natural process in response to climate change from wetter to dryer conditions. A major environmental concern, however, is the rapid expanse of desertification on a worldwide basis as a result of human activity. The main causes of desertification are overgrazing of domesticated animals and deforestation in areas marginal to deserts, adverse soil erosion, poor drainage of irrigated lands, poor farming techniques, overuse of water supplies, and human-induced global warming. Desertification does not occur in a continuous front in most cases but instead advances in patches that expand in an inconsistent ebb and

Maps showing the successive shrinking of the Aral Sea in the Soviet Union and former Soviet Union in 1960, 1984, and 2009. The water was withdrawn for irrigation at a rate faster than it could be replenished. The new dry land is desert, resulting in desertification of the area.

flow. Africa has experienced a huge loss of productive land as the Sahara spreads southward at alarming rates. This situation is largely blamed on overgrazing, which removes the stabilizing properties of the plant roots, but certainly climate change is also a contributing factor. Another poignant example is the Aral Sea in southern Russia. As the result of overuse of water from the Aral Sea, largely for irrigation, it has shrunk to one-third its original size, and the area that was formerly water is now desert. (There is a striking photograph of a fishing boat embedded in sand as far as the eye can see with the words “Forgive us, Mother Aral” scrawled in Russian across the side.)

Desertification causes pollution of soil, water, and air. Sand is blown from the exposed surface onto otherwise productive land, polluting the soil. The additional sand and dust slowly render the soil unproductive. In other cases, fields of sand dunes migrate over productive areas and literally drown the productive soil in sand. Soil with no vegetation and open sand are also much more prone to erosion during precipitation events, which can choke streams with sediment, compromising the water quality. Wind lifts dust off the desert surface, affecting air quality with particulate as well. Devastating dust storms that are common around deserts can cause severe health effects, but the effects can be much more widespread. Windblown dust from deserts has been documented to cross the Atlantic Ocean from Africa to the Americas on a regular basis and even, on occasion, to cross the Pacific Ocean from China to North America.

**deserts** Deserts are regions where the annual rainfall totals are less than 10 inches (25 cm) of precipitation per year. It is a common misperception that deserts must be hot, but only tropical deserts fit this definition. For example, the polar regions are also deserts. They may contain frozen water at the surface, but the amount of precipitation is low and the accumulation rate is extremely slow. They also may be the most harshly polluted relative to the sensitivity of the environment.

### LOCATION OF DESERTS

Most deserts of the world are at 30° north and south latitude and at the Poles. The circulation system of the atmosphere controls these locations. If air falls or is driven toward the surface, the downward force creates a higher air pressure. If the air rises, the upward force creates lower air pressure. High pressure means clear sunny weather, whereas low pressure means cloudy, stormy weather. The reason for this pattern is that air is normally warmer at the

surface and can carry a lot of moisture. As it is swept upward, it cools and the moisture condenses into clouds and precipitation. Air from higher altitudes in the atmosphere is cool and dry. As it falls, it warms up; that means that it has even less moisture than it can hold. It takes a predominance of high pressure on a long-term basis to form a desert.

The Sun is more direct at the equator, and, as a result, the air is warmer and rises. Rising air creates precipitation, and thus the tropical rain forests are located in a band around the Earth at the equator. The Sun is least direct at the Poles, and as a result the air is cooler and falls. The resulting high pressure there is the reason that it is a desert. This equator-to-Pole circulation would form the single circulation cell in each hemisphere if it were not for the rotation of the Earth. The twisting of the atmosphere caused by the Coriolis effect subdivides the single large cells into three smaller Hadley cells. The subdivisions mean that air also rises at 60° north and south latitudes, creating temperate rain forests, and it falls at 30° north and south latitudes, thus creating the deserts of the world.

Other effects may also produce small deserts. If air is forced to rise up a hill or a mountain that is in the way of the weather flow, it is just as if it were rising in a low-pressure system. As it rises and cools, the water vapor in it condenses and it rains all of the moisture out on the slopes of the mountain. As this air continues over the mountain and descends the slopes on the far side, it is the same as if it were falling in a high-pressure system. The dry, cool air heats up, so that it can carry more moisture rather than less, and there is no precipitation. The precipitation on the wet, rising air-side of the mountain is called orographic precipitation, and the dry, falling-air side of the mountain is called a rain shadow. The best example of this occurs in Washington State, where the west side of the Cascade Mountains is a temperate rain forest in large part because of the orographic precipitation. The east side of the Cascades is a desert because it is in a rain shadow.

In order to be able to generate precipitation, there must be surface water for evaporation to take place. In areas where there is all landmass and no ocean, there is very little rain. It is unlikely that technically a desert can be formed purely because of the lack of surface water, but it can be very dry at all latitudes. In these areas, deserts can stretch much farther than usual from 30° north and south latitude lines.

### SEDIMENT TRANSPORT

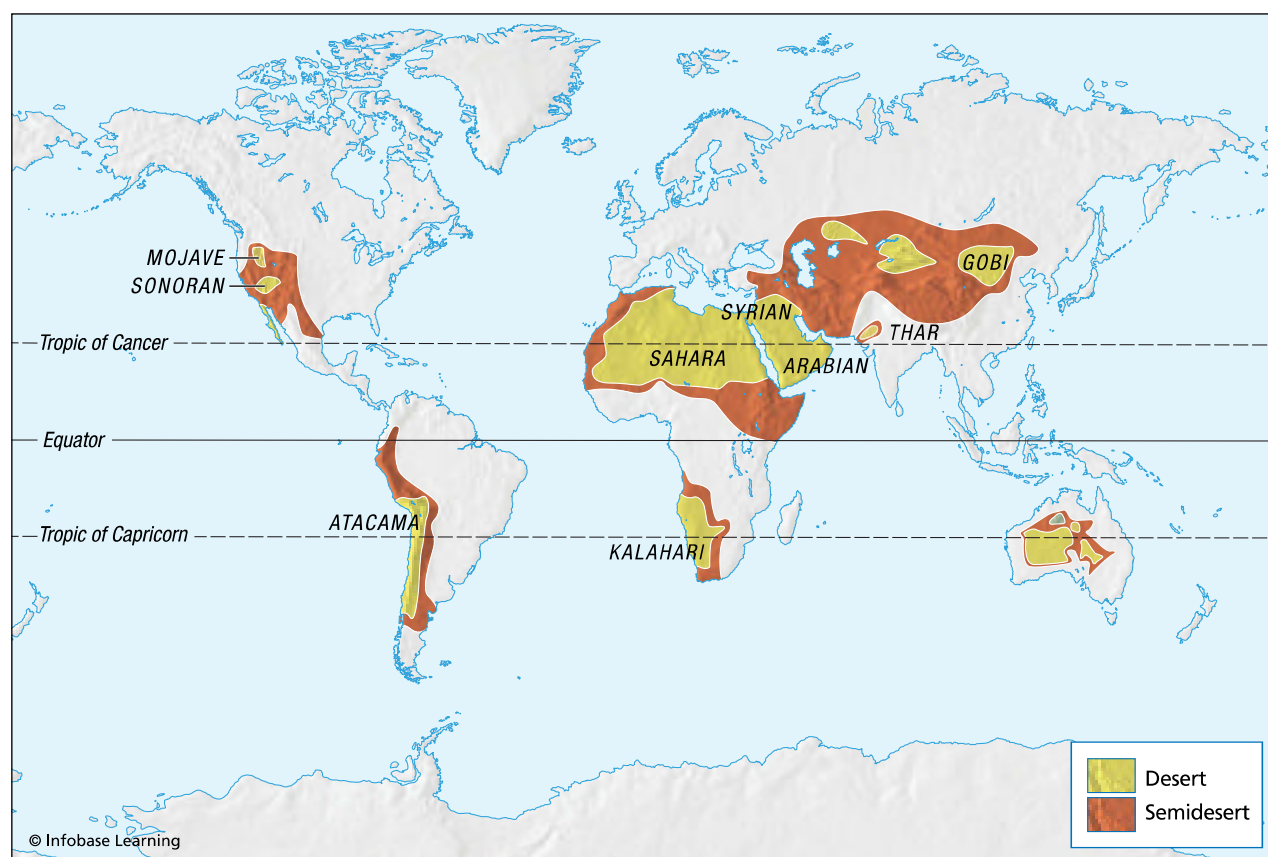

The main differences between erosion and transport of sediments in temperate regions and those in a

desert are vegetation and moisture. In temperate regions with moderate rainfall, both of these factors serve to stabilize the sediment. In deserts, the sediment is used as an effective mechanism of enhanced erosion. The regular daily erosion is primarily accomplished by wind. Unfettered by such sources of friction as trees, houses, and other obstructions, wind can relentlessly sweep over the landscape at high velocities. As in transport in streams, the wind carries sediment in suspension, by saltation (bouncing off the ground surface), or by rolling it along in the surface load. The suspended load is made up of dust and silt and can be carried aloft at heights up to one mile (1.6 km) and spread tens to hundreds of miles downwind of the source region. In some cases, the dust can be transported thousands of miles out of its source region. For example, dust from Africa is commonly found blown all the way to North America across the Atlantic Ocean. This dust is part of the particulate measured in air pollution studies.

The sediment moved in saltation is also part of the surface load. These generally sand-sized grains bounce as they are transported in the wind. Their travel path is generally a series of arcs whose shape depends upon the substrate. They tend to jump about

20 inches (50 cm), but they can rise up to 6.5 feet (2 m) if they bounce off a hard surface. The sand is driven so hard by the wind that it can strip the paint from a car or facet a rock. The rolling sediment is pebble or larger size and cannot be lifted from the surface. In cases where the wind is strong enough to move everything smaller than the pebbles, it can move the finer sediment in a deflation structure and leave a lag deposit of pebbles. The surface pebbles can be fitted and set together and polished by the wind, forming desert pavement. The exposed larger grains are polished flat on the wind side. A multifaceted rock is called a ventifact.

Sand can also be carried by water during the infrequent desert storms. As with the wind, there is much less friction in a desert. Runoff and surface water flow very quickly and form sheet washes and flash floods in the ephemeral streams. The sediment is more readily suspended in the flowing water in a desert because of the velocity and turbulence, but suspension primarily occurs because the sediment is not fixed to the surface as in temperate regions. The entrained sediment makes the flowing water much denser but also a much more effective agent of erosion than clear water. The floods cut deep, steep-walled channels into the desert

Map of the world showing the locations of the major deserts, primarily centering around 30 degrees north and south latitude

**Earth's major atmospheric circulation cells (rotating arrows). Where air rises at the equator and 60 degrees north and south latitude, there is low pressure and consequently plentiful precipitation. Where air falls at 30 degrees north and south latitude and both North and South Poles, there is high pressure and consequently very little precipitation.**

that are dry most of the time. They are called dry washes or arroyos.

### EROSIONAL FEATURES

The heavy wind erosion and intermittent water erosion are strong agents of change for the desert landscape. The sandblasting readily abrades most rock surfaces. Softer materials such as shale weather quickly, whereas more resistant layers do so slowly. It is this contrast in resistance erosion of the different rock types that creates the desert landforms. In areas of flat-lying strata, erosion will progress through layers in depth order. If a less resistant layer

is encountered, erosion will proceed much more quickly. The contrast between the more resistant layers on top and softer layers beneath results in a step pattern from the flat resistant layer with a cliff in the softer layer and a deeper flat area in the next resistant layer down. Erosion proceeds on this feature as wind abrades the softer layer away until the resistant capping layer is undermined and collapses. Slowly, the capping layer erodes away until the landscape height is reduced.

The step-pattern landscape evolves into other characteristic features. If erosion proceeds around the flat area so that it becomes a raised flatland surrounded on two or more sides by a cliff stepping

down, the flat area is called a plateau. As erosion reduces the size of the flat top, it becomes a mesa, a small table-shaped feature with cliffs on all sides. As erosion proceeds, the feature shrinks to a pinnacle or chimney before it erodes away completely. In some cases, two chimneys may still contain a flat slab of caprock across the top. These are called arches. There are other erosional forms such as yardangs, which look like small shrubs with a larger, flat piece of caprock perched atop a thin pinnacle. All of these, however, are just left-over pieces in the grand erosional scheme.

The resistant caprock does not need to be flat lying. It may be tilted in one direction, and, if so, it will erode into another group of structures. For gently inclined strata, there will be a gentle slope on the caprock and a steep slope instead of a cliff. This feature is called a *cuesta*. If the strata are steeply inclined or even vertical, the resistant layer forms a spine, with the weaker layers and rubble or talus forming lower sides. This feature is called a *hogback* because of the resemblance in appearance.

### DUNE FORMATION AND CLASSIFICATION

Probably the most identifiable feature in deserts is the sand dune. These features are piles of sand that have been shaped by wind movement. Sand dunes are initiated on some obstacle to wind flow such as a rock or a shrub. Although the front side of the obstacle experiences high wind velocity, some sand can become trapped beneath it. More sand builds on the obstacle until it buries it in a crescent-shaped dune that can move away from the obstacle in the downwind direction. The dune has gently inclined slope on the upwind, or *stoss*, side of the dune and a steeper slope on the downwind, or *lee*, side of the dune. Sand is carried up the *stoss* side of the dune, which is eroded by the high-velocity wind. Once the sand reaches the top of the dune, it slides down the *lee*-side slope, called the *slip face*. This side is protected from the wind, forming a shadow. The sand accumulates on this side of the dune.

It is this process of eroding sand from one side and depositing on the other by which dunes migrate. The shape of the deposited layers of sand on the *slip face* is originally asymptotic both on the top and on the bottom. During migration, however, the top of the *slip face* deposit is eroded as the *stoss* side migrates over the top of it. The final shape of the *slip face* deposit is sharp on top but asymptotic on the bottom. These deposits left by migrating dunes are called *cross beds*. The *slip face* deposits are called the *foreset beds* or *layers*, and the flattened-off top is called the *topset*. The Navajo Formation sandstones

in the southwestern United States have the best desert-dune-generated cross beds in the world. They are used as illustrations in many textbooks.

Depending upon factors such as velocity of the wind, direction and stability of directions, sediment supply, and grain size, the dunes can take on a number of shapes. Probably the most common of these is the Barchan dune, which retains the shape of the original formation on the obstacle. These dunes are crescent shaped with the two pointed tips pointing in the downwind direction. They are common in areas of flat topography, a single constant wind direction, and limited sand supply. If the wind direction shifts periodically to several directions, a number of Barchan dune shapes will coalesce into a multiply pointed star dune. Where there is an ample supply of sand and only moderate winds in a single direction, large transverse dunes develop. In contrast to the curved shape of a Barchan dune, transverse dunes have long straight crests like ocean waves. If the winds increase in velocity, the straight crests bend and break, forming a crescent to horseshoe shape similar to that of the Barchan dunes called Barchanoid dunes. In very high-velocity winds with ample sand supply, the sand bodies stretch out parallel to the wind direction in thin elongate ridges. These are called longitudinal dunes, or *seif* dunes, from the Arabic word for “sword.” These dunes can reach heights of 325 feet (100 m) and extend in length for several miles. There is one thick sand area in Saudi Arabia called Rub al Khali, where the *seifs* reach 975 feet (300 m) high and stretch for almost 120 miles (192 km). The final type of dunes are parabolic dunes and are also similar to Barchan dunes but with the tips pointing upwind instead of downwind. They are backward relative to wind direction and form in areas where there is enough vegetation present to affect the dune shape. Most dunes are more commonly 100 feet (30 m) in height, but transverse to parabolic *draas* dunes in Saudi Arabia may reach heights of 820 feet (250 m) with wavelengths of two-thirds of a mile (1 km) or more.

### POLLUTION OF THE DESERT

There is some natural pollution in the desert. All of the dust in suspension is particulate made of fine quartz grains. Even in the natural state, inhaled fine quartz can scar the lungs, causing the disease called *silicosis*. This is by far the most dangerous health threat in a desert. Besides this air pollution, there is also some water pollution. With the intense amount of evaporation, any ions in the surface water are quickly concentrated and precipitated as salts onto the sediment. In some cases, calcite may be

precipitated just below the surface to form caliche. In most cases, the precipitants are halite, gypsum, and borax, among others. During subsequent rainfall events, these salts are dissolved into the surface water, at least degrading it if not contaminating it. These salt deposits are deposited in even thicker and more extensive layers in a playa lake. These low, flat lakes form in the spring from runoff but quickly dry out for most of the year. The water in these lakes is generally not potable and a pollutant to any other water sources with which it might have contact.

Deserts are extremely fragile environments and probably least able to absorb pollution even though

they may get the most. The food and water budget is extremely tight for the fragile ecology in the area. Seeds sit dormant most of the year waiting for the rare rainstorm to germinate and go through a complete life cycle before they dry out and die in the unrelenting sun. Herbivorous animals such as jack rabbits depend on the plants, and their population is tightly controlled by the availability of these plants. In turn, the predator population is controlled by the number of herbivores. The lower the availability of water, the more tightly the ecosystem will be constrained. Plants such as cacti grow extremely slowly and are very sensitive to changes in the environment.

Block diagrams showing the six dune types possible in deserts

Human recreational activities such as driving motorcycles and four-wheelers through the desert, a practice that is especially popular in western states such as California, can do irreparable damage to many of these ecosystems.

On the larger scale, because it has few if any people in it, the desert has been chosen by the federal government as the best place to carry out some of the most dangerous operations to people and the environment, namely, military testing and radioactive waste disposal. The Nevada Test Site is the location where nearly 1,000 nuclear tests have been carried out over the past 55 years. At first, tests were at the surface or even in air, but later all were conducted underground. Even underground, the amount of radioactive fallout from these tests is tremendous and now coats the area for tens of miles around the site. The detonation sites themselves are completely destroyed and will remain so for centuries. The government has also tested numerous types of conventional weapons in the desert and still does on a regular basis. Storage of dangerous weapons such as nerve gas and biological weapons is considered to be safer in the desert because, in the event of an accident, there will be less impact on society.

In addition to the direct pollutants from defense testing of conventional weapons such as lead from bullets and phosphorus from incendiary devices, there is pollution from regular release of fuel, solvents, particulate, polycyclic aromatic hydrocarbons (PAHs), and other combustion products from bases and normal operations. This waste can be more damaging to the environment in a desert than in temperate areas because the ratio of waste to groundwater is much higher and, as such, is more bioavailable.

The final type of waste that is specifically disposed of in deserts is radioactive waste. Both the Waste Isolation Pilot Plant (WIPP) and the Yucca Mountains high-level radioactive waste repository are located in the deserts of the southwestern United States. Great precautions have been taken in both cases to prevent leakage of radioactive waste into the environmental systems. They are as safe as possible under the circumstances, but any small leak could be devastating to the areas. The construction of each of these facilities has greatly disrupted the local environment of the areas. It has included disruption of the soil and introduction of pollutants common to construction sites such as solvents, fuel, and various air pollutants.

**diazinon** The pesticide diazinon was found in only 25 of the first 1,678 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List) where it was analyzed, and yet it was rated number 56 of the worst 275 substances on the 2007 CERCLA Priority List of Hazardous Substances. The reason that it is considered so dangerous is that it is one of the top insecticides for incidents of poisoning of humans and wildlife. Diazinon was first restricted in 1988 (restricted use pesticide [RUP]) when the EPA prohibited its use on golf courses and sod farms, among other areas. The restriction was partly removed in 1996, but recently diazinon was more stringently restricted when on December 31, 2004, it was banned from all outdoor, nonagricultural products. Diazinon is also known as Alfatox, Basudin, AG 500, Bazinon, Dazzel, Desapon, Dianon, Diazide, Drexel, Gardentox, Kayazinon, Kayazol, Knoxout, Nucidol, Sarolex, and Spectracide, among about 500 registered products.

## PROPERTIES, USE, AND PRODUCTION

Diazinon is a nonsystemic organophosphate insecticide, acaricide, and nematicide that does not occur naturally. Pure diazinon is a clear, colorless, odorless liquid, but it is most commonly used in agriculture and extermination as a pale to dark brown liquid of 85–90 percent purity. Residential use is most commonly with 5 percent preparations. Other forms include dust, wettable powders, granules, emulsifiable solutions, seed dressings, and agricultural concentrates. It has been used to control cockroaches,

silverfish, ants, fleas, ticks, scavenger wasps, aphids, spiders, worms, grubs, nematodes, and mealybugs and to protect fruits, vegetables, coffee, tea, cotton, tobacco, rice, corn, alfalfa, potatoes, ornamental plants, rangelands and pastures, sod farms, golf courses, and animals, both pets and livestock. It was developed in 1952 for agricultural and residential applications. Approximately 13 million pounds (5.9 million kg) of diazinon was applied annually between 1987 and 1997. About 20 percent of the usage was on agricultural crops and livestock, about 39 percent for turf and homeowner control of insects, 19 percent for lawn care operators, and 11 percent for exterminators. As part of the restrictions, production of diazinon was reduced by 25 percent in 2002 and 50 percent in 2003 with corresponding cancellation of 20 uses on food crops.

### ENVIRONMENTAL RELEASE AND FATE

As with most pesticides, virtually all of the diazinon produced has been released to the natural environment as a nonpoint source pollutant. Only that which is improperly disposed of or spilled during manufacture, transport, or storage is a point source pollutant. Diazinon is primarily released to the soil and enters surface water through runoff and the atmosphere through evaporation. Diazinon has a removal half-life in soil of 14–80 days (average 40) but can persist for six months under low-temperature, low-moisture conditions. It is removed by hydrolysis reactions and microbial activity. Diazinon can slowly leach through soil and contaminate groundwater. It was identified in water from 54 wells in California alone. Diazinon has been most frequently found in surface water that drains residential areas originating in runoff from home and lawn use, rather than in agricultural areas. It has been found in surface waters in 24 states and the District of Columbia and has been the most common pesticide found in surface water nationally. It has also been found in tap water in Canada and Japan. It degrades quickly in most surface waters, with a typical removal half-life of one to six days. In waters with neutral pH, however, one study found it to persist with a removal half-life of 185 days. Diazinon can also enter the atmosphere from spraying and evaporation at rates of up to 25 percent of that applied. A 1995 U.S. Geological Survey study found that air and rain from many urban and agricultural areas had detectable levels of multiple pesticides. Diazinon was found in the most areas with the highest concentration of any of them. It was also one of five pesticides that were found to be capable of concentrating in fog droplets. The states with the high-

est environmental release of diazinon are California, Texas, and Florida.

Diazinon is very toxic to birds (the main reason for the RUP status), mammals, bees, freshwater fish, and aquatic invertebrates. From 1994 to 1998, diazinon had the highest number of bird kill incidents resulting from pesticide exposure and the second highest number of all time. There were reports involving 23 species in at least 18 states. Diazinon had the most ecological incidents for all organophosphates at 21 percent of the total. About 11 percent of the incidents involved aquatic organisms. Diazinon is absorbed through plant roots and translocated throughout the plant. The removal half-life for plants is two to 14 days.

### HEALTH EFFECTS FROM EXPOSURE

Diazinon has moderate toxicity for both animals and humans, rated as a class II pesticide (I is strongest; IV is weakest) by both the EPA and World Health Organization, at full strength. It is a strong blood plasma and brain cholinesterase inhibitor by inhalation, ingestion, or dermal exposure. Acetylcholinesterase is an essential enzyme for normal nerve transmission. Effects of acute exposure to diazinon include headache, muscle weakness and tremors, sweating, blurred vision, pinpoint pupils, slurred speech, labored breathing, slowed reflexes, lapses in memory, slowed heartbeat, salivation, nasal discharge, nausea, vomiting, diarrhea, and abdominal cramps. High doses can induce periodic or continuous convulsions and even cause coma and death. Long-term chronic exposure can cause depression, anxiety, irritability, confusion, muscle twitching, and decrease in body weight, and large doses can damage the pancreas. Diazinon exposure can cause skeletal and spinal deformities in developing bird fetuses and increase the number of stillbirths and neonatal deaths in some mammals. Diazinon is generally not regarded as carcinogenic, even after extensive testing. The only suggestion of a possible cancer link was an epidemiological study that found an increase in non-Hodgkin's lymphoma in farmers in the Midwest, but it is difficult to establish diazinon as the definite cause.

### REGULATIONS ON HUMAN EXPOSURE

To address the numerous adverse health effects from exposure, several federal agencies have established regulations on diazinon. The EPA has established an adult lifetime health advisory for diazinon of six parts per million (ppm) and a one- to 10-day health advisory maximum of 20 ppm in drinking

water. The National Institute of Occupational Safety and Health (NIOSH) limits the workplace to 0.01 milligram of diazinon per cubic meter of air for a 10-hour-workday, 40-hour workweek. Other regulations are under consideration.

**3,3'-dichlorobenzidine** Dichlorobenzidine was used extensively in the synthesis of certain types of dyes for several decades, especially in the 1960s and 1970s, but that application ended abruptly in 1986 with health concerns and the development of superior substitutes. These health concerns primarily center on its potential as a human carcinogen, and, as a result, it is listed as one of only 13 chemicals that have special designation by both the Occupational Safety and Health Administration (OSHA) and the National Institute of Occupational Safety and Health (NIOSH). Dichlorobenzidine is also available as 3,3'-dichlorobenzidine dihydrochloride and 3,3'-dichlorobenzidine salts, among others. Dichlorobenzidine was found in only 32 of the first 1,467 U.S. Environmental Protection Agency (EPA)-designated Superfund sites (National Priorities List) where it was analyzed, but it was rated a very high number,

40 of the 275, substances on the 2007 CERCLA Priority List of Hazardous Substances. It is because dichlorobenzidine is considered to be so carcinogenic by so many federal agencies that it garners such a position in spite of its scarcity.

#### PROPERTIES, USE, AND PRODUCTION

Dichlorobenzidine is a synthetically produced volatile organic compound that is in the category of chlorinated hydrocarbons and does not occur in nature. In pure form, it is a gray to purple solid with a mild odor, but it is commonly used as dichlorobenzidine salt, which is a white crystalline (needles) solid with a faint odor. Dichlorobenzidine was primarily used as a pigment for at least seven shades of yellow as well as some red and orange printing ink, and textiles, paper, paint, plastic, and related items. It also was used in the production of rubber and plastics (curing agent) and as a chemical intermediate in protective clothing manufacture. Dichlorobenzidine was first commercially produced in the United States in 1938. By 1971, domestic production of dichlorobenzidine reached 3.5 million pounds (1.6 million kg) and 5 million pounds (2.3 million kg) in 1972, both of which are not very high. Domestic production never exceeded 10 million pounds (4.5 million kg). As domestic production tailed off in the mid-1980s, imports rose from 208,000 pounds (94,545 kg) in 1979 to 8.7 million pounds (4 million kg) in 2000.

#### ENVIRONMENTAL RELEASE AND FATE

Dichlorobenzidine is most commonly released to the environment as a point source pollutant from a manufacturing, transport, or storage facility as a spill or as a leak from a hazardous waste repository. If it is released to air, the removal half-life is estimated to be 9.7 hours through photolysis (sunlight), although under certain conditions it is said to persist up to 60 days. If dichlorobenzidine is released to water, it will break down very quickly if exposed to sunlight, with a removal half-life of 90 seconds. At deeper levels of lakes and ponds, it tends to bind tightly to particles and settles into the sediments. Removal in these areas is very slow because breakdown by microbial activity is weak. In soil, dichlorobenzidine is very persistent, remaining for several months before it is degraded. Dichlorobenzidine is strongly bioconcentrated by certain aquatic organisms. Bacteria can contain dichlorobenzidine levels 200 to >240 times ambient conditions, but bluegill sunfish can have 1,670 to >2,000 times ambient levels. Predators, including humans, who eat these fish can ingest a

significant dose of dichlorobenzidine. Fortunately, because dichlorobenzidine binds strongly to sediment, bioavailability tends to be low.

According to the EPA Toxic Release Inventory, a mere four pounds (1.9 kg) was released to the environment by industry in 2005. It is reported that 41,861 pounds (19,028 kg) was released in 1998, but 41,600 pounds (18,909 kg) of this was simply transferred off-site for disposal, leaving 261 pounds (119 kg) released directly to the environment. In contrast, some 210,798 pounds (95,817 kg) of dichlorobenzidine was reported released to the environment in 1988, though again, most was simply transferred to an off-site facility.

### HEALTH EFFECTS FROM EXPOSURE

It is the health effects resulting from exposure to dichlorobenzidine that curtailed and, in some cases, eliminated its use. Acute exposure to dichlorobenzidine produces several symptoms related to contact toxicity and central nervous system depression. These symptoms include headache, dizziness, stomachache, sensitized skin, dermatitis, caustic burns, sore throat, upper respiratory tract infection, frequent urination, and blood in the urine. Long-term chronic exposure produces enhanced effects of short-term exposure as well as mild liver damage. When pregnant animals were exposed to dichlorobenzidine, offspring were more likely to have underdeveloped kidneys and develop tumors of the kidneys.

The EPA classified dichlorobenzidine as group B2, probable human carcinogen, and the International Agency for Research on Cancer (IARC) lists it in group 2B, reasonably anticipated to be a human carcinogen. Virtually all evidence for dichlorobenzidine to be listed as a carcinogen is from experiments on laboratory animals, so its danger to humans may not be as great as reported. It was found to produce an increase in cancers of the urinary bladder, kidneys, liver, skin, mammary glands, and Zymbal gland, as well as leukemia. Laboratory studies also show dichlorobenzidine to be mutagenic, resulting in sister chromatid exchange, unscheduled deoxyribonucleic acid (DNA) synthesis, and chromosomal aberrations in several types of cells.

### REGULATIONS ON HUMAN EXPOSURE

Federal agencies have imposed restrictions on public and worker exposure to dichlorobenzidine as the result of the severe health effects. The EPA requires the reporting of any spill of dichlorobenzidine of one pound (0.45 kg) or more to the National Response Center. OSHA and NIOSH list dichlorobenzidine as one of 13 potential occupational carcinogens that

require full respiration gear. Under these guidelines, there is to be minimal to no exposure (“de minimis”) of workers to dichlorobenzidine at any time. The NIOSH 1972–74 National Occupational Hazard Survey estimated that 1,100 workers were exposed to dichlorobenzidine in the workplace.

**dioxin** Dioxin is the common name for a family of organic compounds that are halogenated, the most common of which are the general compounds CDD or PCDD (polychlorinated dibenzodioxin or dioxin) and the related compounds CDF or PCDF (polychlorinated dibenzofuran or furan), the most toxic of which is called TCDD (2,3,7,8-tetrachlorodibenzo-p-dioxin). Dioxin gained its fame as a toxin and environmental pollutant through TCDD because it is the active ingredient in Agent Orange and the most notorious pollutant in Love Canal, New York, among other profoundly polluted sites. CDDs and CDFs form a group of 210 congener com-

pounds (135 CDFs and 75 CDDs), but only 17 of them have chlorine in the proper position to be toxic. There is a rating system called the toxicity equivalence factor (TEF) that is used to rate the toxicity of mixtures of these compounds, which ranges from 0 to 1, where 1 is for pure TCDD. The TEF is used to determine toxic equivalency (TEQ) for exposure studies. Dioxin is the subject of a heated controversy between the U.S. Environmental Protection Agency (EPA) and scientific/health organizations who seek to ban it and the chlorinated solvent industry who rely on it. As a result, dioxin has remained in use for many decades past when it was found to be dangerous. It is a testament to the persistence of the chlorinated solvent industry that they have kept dioxin available when far less dangerous compounds have been banned in a much shorter time.

The most recent case of dioxin in the news occurred when the 2004 Ukrainian presidential candidate Viktor Yushchenko went from a handsome, healthy individual to a disfigured, emaciated dying man over a period of several months while on television on a daily basis. For a long time, poisoning was suspected but could not be proven. It was the constant media coverage of the situation that may have saved Yushchenko's life. It is reported that a toxicologist was watching Yushchenko on television and recognized the symptoms of chloracne. The physician who treated Yushchenko claims that it is the second largest dose of dioxin ever administered to a human.

There are several types of dioxin congeners listed on the 275 pollutants of the 2007 CERCLA Priority List of Hazardous Substances. For example, hexachlorodibenzo-p-dioxin and heptachlorodibenzo-p-dioxin are ranked 153 and 154, respectively. The most dangerous congener, tetrachlorodibenzo-p-dioxin, however, is ranked number 73. Dioxins of all types have been found in at least 126 of the first 1,467 EPA-designated Superfund sites (National Priorities List) where they were tested.

### PRODUCTION AND USE

The history of dioxin began around 1900, when Dow Chemical in Midland, Michigan, began producing free chlorine. Over the next several decades, they would use this chlorine to develop chlorinated hydrocarbons, the production of which blossomed during the 1930s and 1940s. These products would be used to develop modern pesticides and solvents and to provide the basis for the plastics industry. Dioxin is produced both by manufacture of these products and by burning them and as such began appearing in the natural environment as early as the beginning of the 20th century. It was not until the

President Viktor Yushchenko of Ukraine on July 4, 2004 (left), and five months later on December 10, 2004 (right), with face disfigured by reported dioxin poisoning (AP Images)

1940s that large quantities of dioxin began appearing in the environment when it began to be produced on purpose, and it peaked in the 1960s during Agent Orange production and use.

### ENVIRONMENTAL RELEASE AND FATE

The current primary sources of environmental dioxin are coal-fired utility plants, metal smelters, transportation sources and especially diesel trucks, waste incineration plants and other disposal burning, polyvinyl chloride (PVC) and other plastic production, paper mills, treatment and use of sewage sludge, and other industries that use chlorine in processing. Small amounts of dioxin are also released from home furnaces and even from cigarettes, where both the tobacco and the white, chlorine-bleached paper are contributors. Dioxin is primarily discharged into the environment as vapor or particulate in air and is then deposited as fallout or precipitation wash-out. As a result, concentrations are higher near the source, but dioxin can travel long distances as vapor, and, as a result, it has been found in lakes in even remote areas. It settles onto water, sediments, soil, and plants by this mechanism. Dioxin can enter the water system directly through discharge from paper and pulp mills and other industry. It can also enter the natural environment from leakage of old stored material, whether buried or in warehouses.

Once it is in the natural environment, a very small part of the dioxin may evaporate or break down from exposure to sunlight and atmospheric chemicals. In surface waters, dioxin tends to bind to particles and settle into the sediments at the bottom. Dioxin binds strongly to the organic component of soils and is generally immobile. The only way it can move into the groundwater system, in most cases,

is if it is dissolved by another chemical and transported. This process is not uncommon in waste sites, where multiple pollutants are present, but otherwise, it is rare. The problem occurs once the dioxin is in the environment. Dioxin tends to adhere to the surface of microscopic organisms, which are then eaten by larger organisms, thus transferring it up the food chain in aquatic and interacting systems (primarily birds). The persistence of dioxin relative to other chemical compounds causes it to biomagnify with each step, reaching dangerous concentrations at the top of the food chain. Terrestrial plants take up only small amounts of dioxin through their roots, but air pollution fallout can coat their leaves and stalks. Grazing animals eat plants coated with dioxin, which enters their bodies and, in turn, those of their predators. Humans, at the top of these chains, are even more susceptible to dioxin exposure.

The EPA estimates that more than 96 percent of human exposure to dioxin is through diet, with 93 percent from meat and dairy products alone. In a typical American diet, the primary source is the ingestion of beef, followed by consumption of dairy, milk, chicken, pork, fish, and eggs, in decreasing order. In terms of contents, butter and freshwater fish have at least twice the concentration of any other sources besides human breast milk, which is also high. The reason that freshwater fish have high concentrations is that those in the study were farm raised and fed a diet of meat, which is high in dioxin. In these other foods, dioxin tends to be stored in fat, so higher fat content typically translates to higher dioxin exposure. A vegan diet is recommended to prevent exposure to dioxins.

### HEALTH EFFECTS FROM EXPOSURE

There have been extensive studies of the effects of dioxin exposure on animals. These studies indicate numerous adverse health effects including skin disease; reproductive damage, such as decreased fertility, decreased sex hormones, reduced sperm levels, and increased miscarriages and birth defects; immunological damage; endocrine system damage; and developmental damage. Rats and mice developed liver, thyroid, and other types of cancer even when exposed to small amounts of dioxin in food for extended periods. It is definitely carcinogenic to some animals. Monkeys also developed behavioral problems and learning disorders when exposed to low concentrations of dioxin.

There are numerous adverse health effects in humans from exposure to dioxin. The most obvious of the effects is chloracne, a severe skin disease that most commonly occurs on the face and upper body.

In severe cases, it can persist for years and be quite disfiguring. Other effects on the skin can be severe skin rashes and excess body hair growth. Dioxin has also been shown to cause liver damage including inability to metabolize hemoglobin, lipids, proteins, and sugar properly. These effects are mostly reversible, but full recovery can take years. Some studies indicate an increased risk of diabetes and abnormal glucose tolerance indicating damage to the pancreas. Dioxin has also been shown to cause learning disabilities, delay motor skills development, and lower IQ scores in exposed children. Moderate to severe immunological damage has also been found in some studies. These problems are commonly passed from generation to generation because dioxin is so persistent that it takes seven years to remove half of a dose of dioxin from the human body.

### REGULATIONS ON HUMAN EXPOSURE

The World Health Organization's International Agency for Research on Cancer and the U.S. Department of Health and Human Services National Toxicology Program both consider dioxin to be a potent human carcinogen. In a preliminary report, the EPA found that the lifetime cancer risk is increased 1,000 times though exposure to dioxin. Normally, all of these documented and suspected problems would be enough to have a substance banned from use. The chlorinated solvent industry, however, has sponsored a large amount of research that found conflicting and contradictory results to those of the previous studies that issued dire warnings. They have also lobbied elected representatives to protect dioxin and related compounds. As a result of the confusion, there are no laws governing exposure to dioxin, just recommendations and advisories. There are 66 health advisories issued by 21 states that restrict the consumption of dioxin-contaminated fish and game. The EPA has recommended limits on dioxin in drinking water of one nanogram per liter of water per day of single exposure and not more than 0.01 nanogram per liter of water in long-term exposure for children and not more than 0.04 nanogram per liter of water for adults.

**disulfoton** A pollutant that is not common in hazardous landfills nevertheless can be a significant environmental threat. The pesticide disulfoton was found in only seven of the first 1,430 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List) where it was analyzed, and yet it was rated number 38 of the 275 pollutants on the 2007 CERCLA Priority List of Hazardous Substances. The reason for its high ranking is that disulfoton is a widely used and effective pesticide. Pesticides are designed to control pests by poisoning them, but it is impossible to produce toxic substances that are selective enough not to have significant adverse health effects on other organisms, including humans. Disulfoton is highly toxic to many organisms and exposure is high. Disulfoton is also known as Bay 19639, Di-Syston, Dimaz, Disipton, Disulfoton-diethyl, Disyston, Disystox, Dithiodemeton, Dithiosystox, Ekatin TD, ENT-23427, Ethylthiodemeton, Ethylthiometon, Frumin AL, Glebofos, M 74, phosphorodithioic acid, Solvigram, Solivirex, and Thiodemeton, among others.

### PROPERTIES, USES, AND PRODUCTION

Disulfoton is a chemically synthesized organophosphate insecticide/acaricide and nematicide. It is a colorless oil in pure form but available as an emulsifiable concentrate, liquid, granules, pellets, and dust. It is used in both agricultural and residential applications and in control of mosquitoes in

swamps. Agricultural uses of disulfoton are in field crops such as corn, sorghum, alfalfa, cotton, wheat, soybeans, and oats as well as fruits and vegetables such as asparagus, broccoli, brussels sprouts, cabbage, cauliflower, lima beans, string beans, potatoes, peanuts, peas, peppers, and tomatoes. It is also used on nonfood crops such as tobacco, ornamental plants and shrubs, potted plants, Christmas trees, and other nonfruit trees. It is effective against sucking insects including aphids, grasshoppers, leafhoppers, thrips, rootworm, scale, psyllids, leaf miners, spider mites, white flies, mealybugs, wireworm, webworm, and others. Typical annual application of disulfoton in the United States is approximately 1.2 million pounds (545,454 kg). The primary use is on cotton (420,000 pounds, or 190,909 kg), wheat (220,000 pounds, or 100,000 kg), potatoes (180,000 pounds, or 81,818 kg), Christmas trees (80,000 pounds, or 36,364 kg), and tobacco (60,000 pounds, or 27,273 kg).

### ENVIRONMENTAL RELEASE AND FATE

Disulfoton is primarily applied to soils in large agricultural areas and is, therefore, largely a nonpoint source pollutant, although it can also be a point source pollutant if spilled during manufacture, storage, or transport. Disulfoton binds moderately to soil and, as such, in most cases, has a low to moderate persistence. It may break down quickly to its metabolites, sulfoxide and sulfone, by temperature-dependent chemical reactions and microbial activity. The metabolites are also insecticidally active and environmental health threats, and they can persist for long periods. Higher organic matter, high alkalinity, and higher temperatures result in rapid degradation of disulfoton. In paddy soils, the disulfoton breaks down quickly, but the metabolites persist for a long time. The variable soil conditions result in a variable-removal half-life (removal of half of the mass) of 3.5–290 days, which means that it can persist for a long time. Disulfoton typically does not leach deep into the soil depending upon temperature and chemistry, and, as a result, it is uncommon in groundwater. Agricultural runoff, however, can deliver a significant amount of disulfoton to surface water. Chemical reactions and microbial activity, however, remove it relatively quickly, with a half-life of about seven days under alkaline conditions and higher temperatures.

Disulfoton has strong adverse ecological effects. It is moderately toxic to birds but highly toxic to bees, fish, and most other marine and aquatic invertebrate organisms. It has a bioconcentration factor of 460 times ambient levels, which is considered moderate.

Disulfoton is actively absorbed by plant roots and distributed throughout the plant, persisting there for six to eight weeks. This property makes exposure for animals and humans much higher.

### HEALTH EFFECTS FROM EXPOSURE

There are many adverse health effects from exposure to disulfoton. Acute exposure with high dosage through inhalation and ingestion primarily affects the central nervous system, lungs, and gastrointestinal tract. The primary reason for the reactions is that it is a strong cholinesterase inhibitor in humans. Symptoms of acute exposure include sweating, headache, fatigue, tearing and blurred vision, salivation, nausea, vomiting, diarrhea, stomach cramps, coughing, loss of coordination, muscle twitching, confusion, convulsions, pulmonary edema, respiratory paralysis, coma, and death if the dose is high enough. Disulfoton is also a powerful irritant to the skin and membranes. It causes skin rashes and burns, and, in the case of eye contact, it can cause severe burns and even permanent damage, primarily nearsightedness. It may take up to three weeks to recover from the nonpermanent effects. Long-term chronic exposure causes immediately noticeable effects of flulike symptoms, loss of appetite, weakness, irritability, delayed reaction times, anxiety, and memory loss. It has also been shown to increase the likelihood of cataracts in humans. Such exposure has also caused damage to the spleen, kidneys, liver, pituitary glands, and brain in laboratory animals and decreased fertility, smaller litter size, as well as incomplete bone and testes development, and damaged livers and kidneys in offspring when pregnant animals were exposed to disulfoton. There is no evidence that disulfoton is a carcinogen.

### REGULATIONS ON HUMAN EXPOSURE

Although disulfoton is not covered under the Safe Drinking Water Act, the EPA has recommendations for exposure for both children and adults. They recommend a maximum of 10 parts per billion (ppb) of disulfoton in drinking water for children for periods up to 10 days. For longer periods, it should not exceed 3 ppb for children or 9 ppb for adults, but over a lifetime, it should not exceed 0.3 ppb, which is a very low concentration. The EPA requires the reporting of any leak or spill of disulfoton of one pound (0.45 kg) to the National Response Center. The National Institute of Occupational Safety and Health (NIOSH) limits the workplace to 0.1 milligram of disulfoton per cubic meter of air for a 10-hour-workday, 40-hour workweek. The Occupational Safety and Health Administration (OSHA)

has the same limit over an eight-hour-workday, 40-hour workweek.

**Doe Run smelter Herculanum, Missouri 2001 Air Pollution** Lead is a very useful industrial mineral. It is easy to shape, has a low melting point, is resistant to corrosion, has unusual electrical properties, is very dense, and is relatively abundant and, therefore, inexpensive. These properties make it the ideal material for balancing and other weights, ballistic projectiles or bullets, car batteries, radioactive shielding, some paints; as a component for some glass and a chemical additive in some industrial processes; and in hundreds of other uses upon which a modern standard of living depends. In the past, it was even more commonly used, when it was an additive to all gasoline, oil paints, and solder for plumbing and electronics. These uses were discontinued in the 1970s and 1980s for health reasons.

Galena, or lead sulfide (PbS), is a soft, heavy mineral recognized by its distinctive cubic shape (cleavage), dark gray color, and ability to mark paper and other objects (streak). In the United States and many other countries, it is the principal source or ore mineral of lead. In the United States, lead is

most extensively mined in Missouri, Kansas, and Oklahoma. Galena in this region is found in irregular veins and pockets of limestone and other sedimentary rocks, thought to have been deposited by warm, mineral-bearing groundwater forced out of the Ouachita Mountains as they were being tectonically compressed and uplifted more than 350 million years ago.

### BACKGROUND

Missouri received more than its fair share of this galena-rich groundwater. To the east, south, and west of the Saint Francois Mountains, about 40 miles (64.4 km) southwest of Saint Louis, French explorers in the 1700s found thick deposits of galena literally lying on the surface of the ground. It was eroded out of the soft sedimentary rock in which the mineral had crystallized. By the mid-1800s, the easily exploited surface deposits had been removed and underground mining began. Around 1955, a new set of lead deposits was found in a north-south trending zone west of the Saint Francois Mountains, called the Viburnum Trend, named after a small town in the area and sometimes referred to as the New Lead Belt. More than 40 miles (64.4 km) long and up to a half-mile wide (0.8 km), but only 1,000 feet (304.8 m) below the surface, the Viburnum Trend is certainly the United States' and perhaps the world's most important source of galena.

Numerous companies, both small and large, have mined galena in Missouri over the last 200 years. The historic operations of Renault Lead, Palmer Lead, R. Smith & Company, and the St. Joseph Lead Company, the first to develop mines in the Viburnum Trend, have been consolidated into a few large corporations. One of the largest of these is the Doe Run Corporation. Saint Louis-based Doe Run is the third largest lead mining and smelting company in the world. The company also recycles, on an annual basis, more than 150,000 tons (136,078 metric tons) of lead from waste batteries and telephone cables. Doe Run owns facilities in Missouri, Washington, Arizona, and Peru and employs more than 4,000 people. Doe Run operates two fairly modern and efficient lead smelters in Missouri, one in Glover and one in Herculanum. The legacy companies that Doe Run acquired and its own record of spotty environmental compliance have resulted in a lingering and difficult-to-resolve public health crisis.

### CONTAMINATION OF THE SITE

Doe Run's lead smelter in Herculanum, Missouri (current population about 2,800), first began operations in 1892. Currently, the 50-acre (20.2-ha)

facility, located about 25 miles (40.2 km) south of Saint Louis, processes lead ore trucked in from eight Viburnum Belt mines. Present on the Herculanum site are the smelter, a waste slag storage pile, and a sulfuric acid plant, which converts sulfur released during ore smelting into a valuable commercial product. During smelting, some lead is released into the atmosphere. Lead particles also are blown off a pile of waste rock that is 24 acres (9.7 ha) in area and 40–50 feet (12.5–15.2 m) high. In 2005, the Doe Run smelter at Herculanum emitted an estimated 28 tons (25.4 metric tons) of lead to the atmosphere and added more than 750 tons (680.4 metric tons) of lead-contaminated slag and debris to its stockpile on its property.

Although air pollution control devices and changes in operational procedures are helping Doe Run collect and manage these emissions generally in accordance with its Clean Air Act permit, historic operations and periodic upsets have resulted in leads being distributed throughout Herculanum. The geography of Herculanum compounds the problem. Numerous homes abut the smelter's western and northwestern boundaries, within a few hundred yards of the smokestack and slag pile. Most industrial plants have a buffer of unoccupied or commercial property around them, which gives blowing dust or air emissions a chance to settle on the industrial property before entering a residential neighborhood. At Herculanum, there is no buffer strip, and the

Smokestack at Doe Run Company lead smelter near homes in Herculanum, Missouri, 2002 (AP Images)

homes and backyards have been pressed up against the smelter's property line for the past 100 years. They are regularly coated in lead-contaminated dust generated from ore delivery trucks during loading and unloading, storage and disposal of ore and slag, and material processing. Even the long-used access road to the plant contributes to the problem.

A dust sample collected from this access road contained 30 percent (300,000 mg/kg) lead. Missouri health guidelines warn against having direct contact with soil that has a concentration of more than 0.4 percent (400 mg/kg) lead. Subsequent sampling by the Missouri Department of Health and Senior Services (DHSS), U.S. Environmental Protection Agency (EPA), and other government agencies found high levels of lead to be everywhere in Herculanum, including on door and window sills, in schoolyards and backyards, and even in vegetables in local gardens.

### HEALTH CRISIS AT THE SITE

Lead is toxic to humans. It damages the central nervous system, particularly in the young and unborn, and exposure to elevated lead levels can result in anemia, premature birth, decreased mental ability, low birth weight, and reduced growth. Adults also can be affected, and the most common symptoms consist of decreased reaction time and weakness in fingers, ankles, and wrists. Lead also has been shown to cause cancer in lab animals. Current federal guidelines recommend blood lead screening for all children between six months and six years of age and require medical monitoring and treatment for children with blood lead levels of 10 micrograms/deciliter (10 mcg/dL) or more.

Public health surveys conducted in 2001 examined blood lead levels of 935 people living next to and close by the Doe Run smelter. Of the almost 120 children younger than six years of age who were tested, 28 percent had blood lead levels known to cause adverse health effects. Concentrations of lead in their blood ranged from 10 mcg/dL to 31 mcg/dL. Older children, between six and 17 years of age, fared better: Only 13 (8 percent) had blood lead levels above 10 mcg/dL, with the highest reported value 19 mcg/dL. Overall, within one-half mile (0.8 km) of the smelter, 50 percent of the children tested had unsafe blood lead levels.

On the basis of these data, as well as an examination of conditions within the town, the DHSS concluded that the residents of Herculanum have been exposed to lead in the past and that exposure is ongoing and likely to continue into the future. DHSS classified the site as an "urgent public health

threat" and recommended that immediate steps be taken to develop and implement mitigative measures, particularly focused on young children, to reduce exposure to the lead present in the soil and air at Herculanum.

### REMEDIAL ACTIONS

Yielding to pressure from both federal and state regulatory agencies and the local community, Doe Run began to take steps to address the problem. It purchased 26 homes of families within a half-mile (0.8 km) of the plant who had children less than six years old and made purchase offers on another 134 homes in the same area. Doe Run funded a community education program, warning people of the dangers of lead and stressing the importance of consistently practicing good personal hygiene, including frequent hand washing, regularly cleaning outdoor playground equipment, and avoiding dusty areas, as well as encouraging periodic blood level testing for children. The company expanded a program it began in the 1990s to dig up and replace topsoil in backyards that contain elevated concentrations of lead.

As a company, Doe Run continues to struggle with its obligation to address the environmental and public health issues created by its own operations, as well as those it inherited from predecessor companies. Its critics say that Doe Run has been slow to respond and has only reluctantly implemented solutions imposed by regulatory agencies to deal with the crisis in Herculanum. However, the company is walking a monetary tightrope. It needs to balance its fiduciary obligations to its shareholders and employees to remain a profitable and growing business with demands to implement a financially overwhelming set of cleanup obligations immediately. How that dynamic plays out will, in large part, determine the ultimate environmental fate of Herculanum.

**Donora Killer Fog Donora, Pennsylvania October 30, 1948 Air Pollution** In his radio broadcast of Saturday, October 30, 1948, the famous commentator and reporter Walter Winchell focused the attention of his nationwide audience on the worst air pollution disaster in America since the 1930s dust bowl. Using his trademark staccato, rapid-fire delivery, Winchell vividly portrayed the pain and suffering that the residents of Donora, Pennsylvania, were experiencing from a freakish “killer fog.” Unlike the dust bowl, however, this disaster resulted from industrial pollution. This event would be one of the predecessors of those in the 1950s that inspired the American environmental movement.

## BACKGROUND

Donora, Pennsylvania, had a population in the 1940s of around 14,000 and was a working class/industrial community about 40 miles (64.5 km) southwest of Pittsburgh. Nestled in a picturesque valley of western Pennsylvania, Donora proudly boasted being the home to two of the largest metalworking mills in the United States, the Donora Zinc Works and American Steel & Wire, both owned by U.S. Steel Corporation. This almost four-mile- (6.4-km-) long industrial complex hugged a horseshoe-shaped bend of the western side of the Monongahela River, adjacent to and upwind of Donora’s downtown and residential area. These plants, employing some 6,500 men and women, turned iron and zinc ores into steel, nails, fencing, wire, and other finished goods.

The small valley that the Monongahela River had carved out of the limestone bedrock had a smooth flat bottom, about one mile (1.6 km) wide, protected by hills that rose almost 500 feet (152.4 m) above the river’s surface. Industry was first attracted to this area because of its proximity to Pennsylvania’s coal mines and the ease with which coal and other raw materials could be delivered, and finished goods shipped, up and down the Monongahela. In the early 1900s, the first steel mill opened, and, by 1916, the glow of blast furnaces, stench of sulfur, and steady parade of river barges would dominate the lives of the townspeople for the next 40 years. The citizens

of Donora were mostly immigrants seeking high-paying jobs in the mills.

The production of the mills was staggering. Donora claimed to be the largest maker of nails in the world. This was postwar America, the peak of the country’s manufacturing prowess, with Donora a major part of that industrial juggernaut. Coal, at volumes up to 40 barge loads per day, was necessary to keep this mighty economic engine running. Coal fired the red-hot, open-hearth furnaces, ovens, and vats where the iron and zinc were melted. Impurities from these processes, mostly sulfur oxides but also zinc, fluoride, and other metals, as well as coal ash and soot, were collected and discharged through a series of 150-foot- (45.7-m-) high smokestacks. Residents would often gather in their backyards in the evening to watch the spectacular sunsets brought on as the waning daylight was reflected off the particulate suspended in the air. In the 1940s, such air pollution control devices as baghouses or scrubbers were unheard of, and most people, not only in Donora, but also in Pittsburgh, Detroit, Cleveland, and other major industrial American cities, were content to trade an occasional foul smell or dead front lawn for a steady paycheck.

## THE AIR POLLUTION EVENT

Donora was no stranger to the ill effects of air pollution. Since the 1920s, the mill owners and operators quietly paid claims for damages to crops and livestock originating from the factories. As early as 1918, the zinc works compensated nearby residents for health care costs related to breathing in the noxious fumes and mists released by the plant. Nothing, however, prepared the town for what began in the early morning hours of October 26, 1948, and continued for the next four days. On the crisp autumn evening of October 25, a blanket of cool, dry air silently settled over the town and created a very effective seal. The sulfur oxides, metals, and particulates being discharged out of the low smokestacks started to build up and began to reach dangerous levels. The cliffs surrounding Donora are 500 feet (152.4 m) high, yet the smokestacks were less than 200 feet (61 m) tall. As the next day began, the effects of this temperature inversion started to be noticed.

The air began to turn yellow and then gray. By Friday, October 29, most of the town was covered with a dark haze that seemed just right for the annual Halloween parade. The next morning, nine elderly residents of Donora were found dead in their homes, asphyxiated as they inhaled a fine mist of sulfuric acid formed when the sulfur oxides mixed with

Donora, Pennsylvania, 1948 (Alfred Eisenstaedt/Time & Life Pictures/Getty Images)

water vapor in the air. The following day, police and fire department officials announced an increase in the death toll to 18. The Saturday afternoon high school football game was played in a dense fog, with the crowd unable to see either the players or the action on the field. By midafternoon, it was unsafe to drive and those brave enough to venture outside could not see their own shoes.

Doctors began to urge those who had respiratory problems to leave town, but as many residents tried to flee, the fog and congested streets made an orderly evacuation impossible. By Sunday, the town's funeral home had run out of caskets. Firefighters were called out to go from house to house to give those struggling to breathe a few quick swallows of oxygen from their air packs before moving on to the next home. Incredibly, the zinc and steel mills kept operating throughout most of the disaster, pumping more and more contaminants into the air. It was not until early Sunday morning that U.S. Steel grudgingly gave the order to shut down the plants. By then, 20 people between the ages of 52 and 85 had died, and the town had opened a makeshift morgue

in the community center. More than 7,000 people, over half the population, were ill with headaches, stomach cramps, and vomiting.

Late Sunday afternoon, the weather finally broke, and a rainstorm slowly washed most of the pollution out of the air. The mills promptly reopened. Another 50 residents died within a month of the disaster, but these fatalities were never officially attributed to the "killer fog." U.S. Steel settled lawsuits without admitting blame by calling the fog an "act of God." For the most seriously injured, settlement amounts ranged from \$1,000 to \$30,000. Concentrations of airborne sulfur dioxide were estimated to have been between 1,500 and 5,500 mcg/m<sup>3</sup>. Today's regulations prohibit the discharge of sulfur dioxide at concentrations greater than 80 mcg/m<sup>3</sup>.

### THE AFTERMATH

A series of investigations began within a few months of the disaster. The U.S. Public Health Service, U.S. Steelworkers Union, and Pennsylvania Department of Health all collected data, took extensive health

histories, and tried in a scientific manner to determine what happened. Some of these and other studies were criticized as being incomplete, inaccurate, or not rigorously performed. This, however, was the first time an organized effort was made by governmental agencies in the United States to document the effects of air pollution on public health.

It was Donora that placed the issue of clean air on the national agenda. As a result of the disaster, in 1955, Pennsylvania passed the first air pollution control law in the United States in direct response to the catastrophe at Donora. The Donora smog, as well as other air pollution events, led to congressional hearings on air quality in the United States and, eventually, the Clean Air Act of 1963.

The Donora mills closed in the late 1960s, unable to compete with cheaper overseas labor and energy and more modern plants. Donora's population decreased to less than half, as people left town in search of better opportunities. Today, a beautiful bronze marker, erected in what was the center of the now-demolished Donora Zinc Works, tries to honor those who died in the 1948 disaster. Their real legacy, however, is some of the strictest air pollution control laws in the world.

**Dover Air Force Base Dover, Delaware 1983–present** *Water Pollution* In 1939, the City of Dover, Delaware, made a \$35,000 investment that

would grow into Delaware's third largest industry. With some prodding by the Federal Civilian Aviation Administration (later to become the Federal Aviation Administration, or FAA), Dover purchased 587 acres (237.6 ha) of scrub forest and farmland about three miles (4.8 km) southeast of downtown and slowly began developing Dover Municipal Airport. By March 1941, the "airport" consisted of three hard-surface runways and a foundation for a hangar. Nine months later, the Army Air Corps leased the barely completed facility, and bomber squadrons were using it as they flew antisubmarine patrols along the East Coast during the early days of World War II. Today, some 3,800 active-duty military and civilian employees live and work on the 4,000-acre (1,619-ha) Dover Air Force Base (Dover AFB), supporting such missions as the evacuation of Americans from Iran in 1979; the airlifting of troops, equipment, and humanitarian aid to Somalia in 1992; and the massive Desert Shield/Desert Storm airlifts in 1990. Dover AFB contributes more than \$470 million to Delaware's economy, and its capital assets and aircraft-related equipment add \$5.8 billion to the value of America's defense resources.

#### CONTAMINATION AND INVESTIGATIONS

During its operational life as a very active and fairly compact military installation, materials used in the operation, repair, and maintenance of aircraft and base facilities were spilled or discharged onto the ground. Dover AFB managed these wastes in accordance with general industry practices at the time, which did not place a premium on the environmental consequences of how these types of materials were handled. The main types of wastes generated included spent industrial solvents and petroleum hydrocarbon-related compounds (e.g., waste oil and fuels), but pesticides, plating wastes, and paints also were generated. In 1989, Dover AFB was placed on the National Priorities List (NPL) as a Superfund site so that the U.S. Air Force (USAF) could more effectively investigate and remediate its environmental issues within the framework of this national program and ensure close cooperation with the U.S. Environmental Protection Agency (EPA) and the Delaware Department of Natural Resources and Environmental Control (DNREC). Subsequent to NPL listing, USAF entered into a Federal Facility Agreement (FFA) with EPA Region III and the DNREC to establish an overall approach for completing remedial activities at the base.

One of the first environmental investigations initiated at the base began in 1983 and was related to assessing potential groundwater impacts of an

on-base landfill that had been used for the disposal of construction and demolition debris. Since then, some 20 operable units, which encompass almost 60 different locations, have been identified as having the potential to contain hazardous wastes or hazardous waste constituents. These sites have been grouped into four major waste management units, the East Management Unit, the North Management Unit, the West Management Unit, and the South Management Unit. Nine areas of groundwater contamination (called Areas 1 through 9) also have been identified, and they have been added to the waste management units. A brief summary of each waste management unit is provided in the following:

#### **North Management Unit**

This area includes runways, taxiways, access roads, and open fields, with its main feature a drainage ditch that received unprocessed industrial wastes in the 1950s and treated industrial wastewater in the 1960s. Since 1969, the ditch has been used only for the drainage of storm-water runoff away from the North and West Management Units.

#### **East Management Unit**

This unit is made up of an ammunition storage facility and a hazardous cargo storage building. Overall it contains nine hazardous waste disposal sites and

also includes Area 1, a groundwater plume associated with previous waste disposal activities. The major constituents of this plume are chlorinated solvents and their breakdown products.

#### **South Management Unit**

This unit comprises 10 sites, which include landfills, a fire training area, fuel releases, oil/water separators, underground storage tanks, and a hazardous waste storage area. Three different plumes of contaminated groundwater are associated with the South Management Unit, two containing chlorinated solvents and the third made up of vinyl chloride and benzene.

#### **West Management Unit**

This unit is the largest and contains 40 sites and five areas of contaminated groundwater. Aircraft parking aprons, base housing, shops, a golf course, and administrative offices are within this management unit. Contaminant sources vary; they include landfills, a fire training area, miscellaneous fuel releases, oil/water separators, a pesticide storage and handling facility, underground storage tanks, several former industrial waste basins or ponds, an industrial waste collection drain system, and the former wastewater treatment plant. Contaminants found in the groundwater plumes are related to either petroleum hydrocarbons or chlorinated solvents.

**Air Force C-17 lands at Dover Air Force Base, Dover, Delaware** (Alex Wong/Newsweek/Getty Images)

## REMEDIATION OF THE SITE

Remedial actions at Dover AFB have been focused on addressing the control and spread of contamination from each of the management units. Cleanup activities have removed grossly contaminated soil from landfills, excavated buried drums from a fire training area, and decommissioned a concrete basin along with associated sludge and soil that had been used as part of the base's wastewater treatment operations. The majority of the oil/water separator systems at the base have been removed or replaced and upgraded. Groundwater plumes have been defined and are being monitored so that off-base users are not being placed at risk.

Dover AFB has been diligent (with some periodic prodding by the regulatory agencies) in investigating and assessing potential off-base impacts related to its former waste management practices. In 1984, volatile organic compounds (VOCs) were detected in groundwater from supply wells at a trailer park and other off-base, private properties southwest of Dover AFB. Even though contaminants were below levels at which adverse health effects were expected to occur, and it is likely that contaminants released from a local gas station and dry cleaner may have contributed to the levels of reported VOCs, both the trailer park and several other residences and businesses were connected to the municipal water system by Dover AFB.

Three ball fields that had been part of a landfill for the base were investigated to determine whether they pose a threat to the children and adults who use them. This landfill was used for disposal of construction debris and household refuse in the 1950s and 1960s. An investigation of soil gases being emitted through the cover of the landfill found that levels were so low that no further action was warranted and that the use of the landfill for recreational purposes did not entail a significant risk to children or adults.

More than half of the individual hazardous waste disposal sites have either been recommended for no further action or remediated to cleanup standards. Impacted groundwater is being addressed either through monitored natural attenuation, separate-phase recovery, or accelerated anaerobic bioremediation. The EPA has approved cleanup plans for each of the 20 operable units, and they are in various stages of remedial design, construction, or implementation.

For example, Building 719 is tucked away in a corner of Dover AFB. Inside this building, jet engines were cleaned, repaired, upgraded, and tested. Essential to these activities was the liberal use of chlorinated solvents and degreasers, primarily trichloroethylene (TCE), trichloroethane (TCA),

and dichloroethane (DCE). These solvents, however, were not always handled carefully, and soil and groundwater beneath the building became contaminated, probably as a result of a leaky underground storage tank and a faulty industrial sewer system. In 1997, the Bioremediation Consortium of EPA's Remediation Technology Development Forum (RTDF) selected Building 719 as the first test site for the use of cometabolic bioventing. The RTDF was formed in the early 1990s to encourage joint public-private sector development of innovative remedial technologies.

During the RTDF's initial study, about half of the 84 soil samples collected within a 500-square-foot (46.5-m<sup>2</sup>) test plot found that the contaminated area around Building 719 contained concentrations of TCE, TCA, and DCE greater than 0.25 mg/kg. Contamination was present above the water table and within 10 feet (3 m) of the surface. The Delaware soil standard for the protection of groundwater limits TCE and DCE concentrations in soil to 0.028 mg/kg and 0.029 mg/kg, respectively.

When petroleum hydrocarbons and chlorinated solvents are present in the subsurface, a natural degradation process called cometabolism or cooxidation can occur. Cometabolism is the simultaneous utilization of two compounds, in which the degradation of the second compound (the chlorinated solvent) depends on the presence of the first compound (the petroleum hydrocarbon). During aerobic processes, bacteria generate monooxygenase (MO) and dioxygenase (DO) enzymes that serve to metabolize the petroleum hydrocarbon. These enzymes break up the petroleum hydrocarbon so that the bacteria can use it as a food source (a substrate, or electron acceptor).

Chlorinated solvents have chemical structures similar to those of petroleum hydrocarbons, and the MO and DO enzymes have been found to catalyze the chlorinated solvents that are mixed in with the petroleum hydrocarbons. This process is called a fortuitous reaction, because the bacteria cannot use the chlorinated solvents' transformation products as a substrate (food source) and gain no nutritional benefit from the breakdown of these compounds. The reason that the bacterial enzymes degrade the chlorinated solvents is still somewhat unclear. The cometabolic or cooxidation reactions are thought to inhibit the eventual formation of harmful chemicals, or the bacteria may need some type of secondary enzyme produced during this process. On a practical level, it can serve as an effective remedial technique.

Cometabolic processes work best when bacteria release enzymes during the degradation of a petroleum hydrocarbon. Researchers decided to

add petroleum hydrocarbons in the subsurface at Building 719 because none was present in significant quantity. After testing a variety of compounds, they selected propane as the easiest to introduce and the one that would not further degrade soil or groundwater quality. Three injection wells were installed in the test plot, and, in June 1998, a dilute mixture of propane of about 0.1–1 percent, well below its explosive limit, and air was pumped into the vadose zone-contamination at one location for 14 months. Prior to system start-up, a helium tracer test was done to make sure that injection wells and soil gas monitoring points were properly functioning and correctly positioned to recover unmetabolized propane vapors. The system was monitored every week.

When operations were halted in September 1999, a second set of soil samples was collected. As researchers waited for the TCE and DCE test results, they noticed that chloride concentrations in postremedial soil samples were high. This was a strong indication that the chlorine atoms had been stripped off the solvents and had joined with other ions (sodium and potassium) to form salt in the soil. If so, the bacteria would then be able to degrade the solvents actively. When the TCE and DCE data arrived, concentrations in most soil samples were below laboratory detection limits, and the effectiveness of a new remedial technology had been demonstrated. Cometary remediation has since been refined to the point where nonpetroleum-based electron acceptors can be added to the subsurface to induce the fortuitous reactions needed to metabolize chlorinated solvents. Such substrates (carbon sources) as lactate (sugar water), molasses, or ethanol are regularly introduced to contaminated soils to stimulate the enzyme production needed to break down TCE, tetrachloroethylene (PCE), and other chlorinated solvent compounds as part of the bioremediation process.

#### dust bowl Central United States 1930s Air Pollution

There have been only a few landmark, far-reaching environmental events that fundamentally changed the way people interact with their environment on a national and sometimes a global scale. The Donora, Pennsylvania, "Killer Fog," Exxon Valdez spill, and Love Canal pollution would be on most environmentalists' lists, along with such non-catastrophic events as Rachel Carson's book *Silent Spring* and Al Gore's popularization of the idea of climate change in *An Inconvenient Truth*. Despite the drama, tragedy, and pain that accompany most environmental disasters, only a few have directly affected more than just those living in the immediate area. These occurred in Bhopal, India; in 1952 in London (smog); in Chernobyl, Ukraine; in Linfen, China; and, during the 1930s, in the seven states of Oklahoma, Texas, Kansas, Colorado, Nebraska, South Dakota, and New Mexico, as well as parts of Canada, that collectively became known as the dust bowl.

#### BACKGROUND

When the vast plains of the central United States first opened to settlement, they were covered by deep-rooted natural grasses. These grasses clung tightly to the soil and had evolved to survive in the dry, cold, and windy conditions that were more typical for this part of the country than the wet, warm years of the mid-1800s. As farmers replaced the grasses with corn, soybeans, and alfalfa, the soil became less cohesive and attached to the land, so that, by the early 1930s, all that were required to create the dust bowl would be a drought and some wind.

For almost a century, the central United States enjoyed a period of above-average annual rainfall and fairly moderate temperatures. This, combined

Dust bowl cloud descends on Rolla, Kansas, April 14, 1935 (Franklin D. Roosevelt Presidential Library and Museum)

with the need for extra agricultural production that accompanied World War I, increased the demands on farmers to produce more food and to cultivate parts of their land that they would normally have left fallow. These areas were close to stream-banks, on steep ridges, or in areas covered with trees. This intense level of agriculture was combined with a number of very poor farming techniques including practicing no rotation of crops, plowing entire fields after each harvest, and allowing animals to graze off stubble and other crop residues.

### THE DROUGHT AND DUST STORMS

Although periods of low rainfall occurred in 1890 and again in 1910, nothing matched the enormous drop in precipitation that took place between 1926 and 1934. Areas that typically received 30–40 inches (76.2–101.6 cm) of rainfall per year were getting 40–50 percent of those amounts. Although the reasons behind this drought are not fully understood, recent research suggests a change in the jet stream and ocean currents may have made critical alterations to atmospheric circulation and moisture patterns. It was not until the early 1940s that precipitation levels in this area would again approach predrought levels.

As the fields dried, wind picked up the loose soil and moved it as massive, blowing clouds of dust. Without trees or grasses to hold the soil in place

or breaks to slow the wind, the blowing topsoil drifted like snow. In some places it settled over farms in layers of three feet (1 m) or more and turned once-productive fields into barren wastelands. In 1932, 14 dust storms were recorded on the plains, and, by 1933, the number was up to 38 storms. By 1934, more than 100 million acres (40.5 million ha) of prime farmland had lost all or most of the topsoil to the winds. The worst of the storms took place on April 14, 1935. This Black Sunday gave the dust bowl its name. With wind speeds of 60 miles per hour (96.6 km/h), dust blocked out the Sun, traffic came to a standstill on the roads, and a layer of dust that could be measured in inches penetrated into every home in the area, regardless of how well sealed. The Black Sunday storm blew eastward, depositing a layer of dust over Chicago that equaled four pounds (1.8 kg) for every person living there. It made its way into New England, New York City, and even Washington, D.C., where legislators experienced firsthand, although greatly diluted, what almost a third of the United States was going through. It was after this storm that an Associated Press reporter used the term *dust bowl* for the first time to describe what was happening to the central plains of the United States.

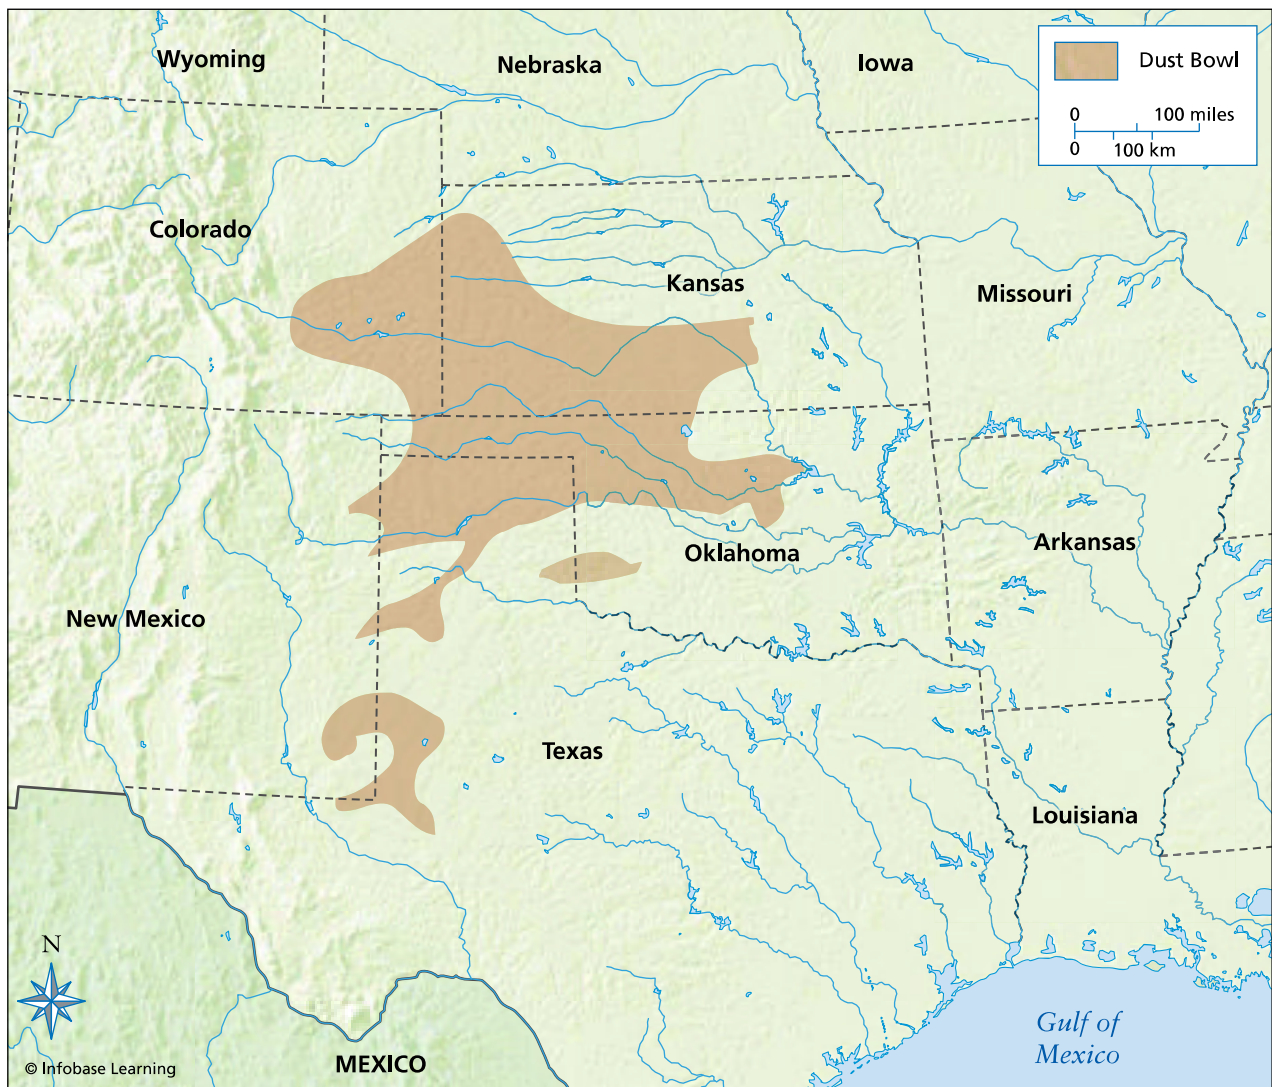

The human costs associated with the dust bowl were enormous. Many of the industrialized parts of the United States had begun to feel effects of the stock market crash of 1929 and the beginning

of the Great Depression, but the central plains had been somewhat insulated from that economic disaster. Farmers grew their own food and managed to maintain a reasonably unchanged, if unglamorous, lifestyle. As the dust bowl literally blew away their livelihood, and they could no longer make mortgage and tax payments, many had no choice but to abandon their homes and seek a new life somewhere else. The largest mass migration in American history took place as a result, and, by 1940, more than 2.5 million people had left their homes in the plains states and settled elsewhere. Some 15 percent of the people in Oklahoma left the state, many moving westward and settling in California. Other parts of the country tried to cope with the influx of dust bowl refugees, called “Okies,” even though they were from many different states. The Great Depression, however, was

in full swing, and these transient newcomers stressed local relief services and competed with long-time residents for jobs, often offering to work for greatly reduced wages.

### REMEDIAL ACTIONS

The government response was slow, but eventually political leaders realized that much of the country’s farmland was blowing into the Atlantic Ocean and started to take action. Congress formed the Soil Conservation Service (now the Natural Resource Conservation Service) in 1935, and it began to study and implement cultivation techniques to reduce topsoil erosion by wind and water. As President Franklin Roosevelt’s New Deal legislation began to pass, the Works Progress Administration (WPA) and other

Map of the south-central United States showing the locations of dust storms or dust conditions during March 1936

newly formed government agencies began to provide emergency supplies, cash, and livestock feed, and transport to maintain the basic functioning of livelihoods for farmers and ranchers. Health care facilities were established and medical supplies provided to meet emergency medical needs of those communities most deeply affected. The government set up reliable markets for farm goods, imposed higher tariffs on imported foodstuffs, and established loan funds for farm market maintenance and business rehabilitation. By 1934, congressional appropriations for drought relief exceeded \$500 million.

As the 1930s came to an end, additional soil conservation measures and policies were implemented. Water supply and irrigation systems were upgraded, and a federal crop insurance program was instituted. The average size of farms increased, and low-yielding, ecologically sensitive, and buffer lands were removed from production. These and other soil conservation programs helped to mitigate the effects of future droughts and establish a pattern of soil conservation measures that made the United States the most agriculturally productive country in the world.

### CURRENT CONCERNS

The agricultural leadership that the United States has achieved is being threatened. The highly mechanized and chemically intensive tools and techniques that were developed in the 1930s and 1940s in response to the dust bowl are now being challenged as concerns increase over the “carbon footprint” of farms and the effects of pesticides and fertilizers on

human health and the environment. This concern is occurring at a time when growing populations, which are expected to double by the end of the 21st century, will place increasing demands on agricultural resources. New techniques such as no-till farming, genetic manipulation of high-yield cereal hybrids, and organic growing methods are currently under development and, in combination with sustainable soil management practices, may offer a way to secure a safe and reliable food supply.

# E

**earthquakes** In addition to being devastating in terms of loss of life and property, strong earthquakes can produce an environmental impact that is felt for years. In many cases, the environmental effects pale in comparison to the damage and death from the earthquake itself and as such are overlooked. Typically, only the contamination of the water supply and resulting disease are ever described in the media. One reason for this lack of comprehensive reporting may be that the United States has been spared any disastrous earthquakes in recent history. Just as long-term effects of environmental contamination from the collapsing World Trade Center in the 9/11 disaster are now being felt by those who participated in the recovery efforts and will appear in the rescue workers of Hurricane Katrina, the same health consequences commonly impact those who have experienced a major earthquake.

## MAJOR EARTHQUAKES

Scientists classify an earthquake by its magnitude, which basically translates into its strength. Early efforts to measure the power of an earthquake were based upon damage to structures and the perception of witnesses. This measure is now termed intensity rather than magnitude, and, at present, the Modified Mercalli scale is the accepted method of measuring the intensity of earthquakes. It rates intensity from I to XII and reflects the magnitude as well as location of the earthquake in terms of geologic materials, building construction, and population density. Although magnitude is used to define an earthquake, for purposes of pollution, intensity, or

the damage caused at the surface, may be the more important designation. Magnitude measures the amount of energy released in an earthquake through the use of instrumentation-based observations of the energy of waves as they pass through the Earth. The initial and most famous catalogue of these ground motions is the Richter scale, which was devised in 1929 after the first reliable seismographs had been developed. The Richter scale is a logarithmic scale based upon the measured amplitude of the strongest waves released by the occurrence of an earthquake and taking into account the types of rock and soil through which they pass. In an attempt to characterize the total energy released by the earthquake better, the moment magnitude scale was developed; it uses ground acceleration or the movement caused as the waves pass through the Earth. Moment magnitude is the current standard for earthquake strength. A new technique being considered for use as a measure of earthquake intensity is Shakemap. Developed by the U.S. Geological Survey, Shakemap measures intensity from ground acceleration over a given area during a major earthquake.

There are numerous major earthquakes every day all around the Earth. The vast majority of these cause very little environmental pollution. They occur in remote areas or beneath the ocean with deep enough foci that they do not generate tsunamis. Although major earthquakes that occur under these conditions typically do not threaten population centers, others closer to developed areas that have intensities above IV or V on the Modified Mercalli scale may be causative or contributing factors for certain types of pollution events. Such events may be the destruction of human structures or other types of damage.

### PARTICULATE HAZARDS

The Lisbon earthquake of 1755 is reported to have raised so much dust that it blocked out the Sun. This is not the only historical earthquake that is reported to have raised surface dust into the air. In this case, however, blocking out the Sun required a large, dry, dusty area that would allow the shaken ground particles to be quickly dispersed into the atmosphere. A description of the Assam 1897 earthquake in which rocks on roads were said to vibrate “like peas on a drum” illustrates the effect of surface waves on particles on the surface. As the energy waves released by an earthquake pass through an arid, unvegetated region, the loose soil and silt at the surface are disturbed and thrown into the air. This is similar to the way a car driving down a dry, unpaved road leaves billowing clouds of particulate behind it. Many major earthquakes occur in moist and vegetated areas, and significant amounts of dust generation are not usually associated with them.

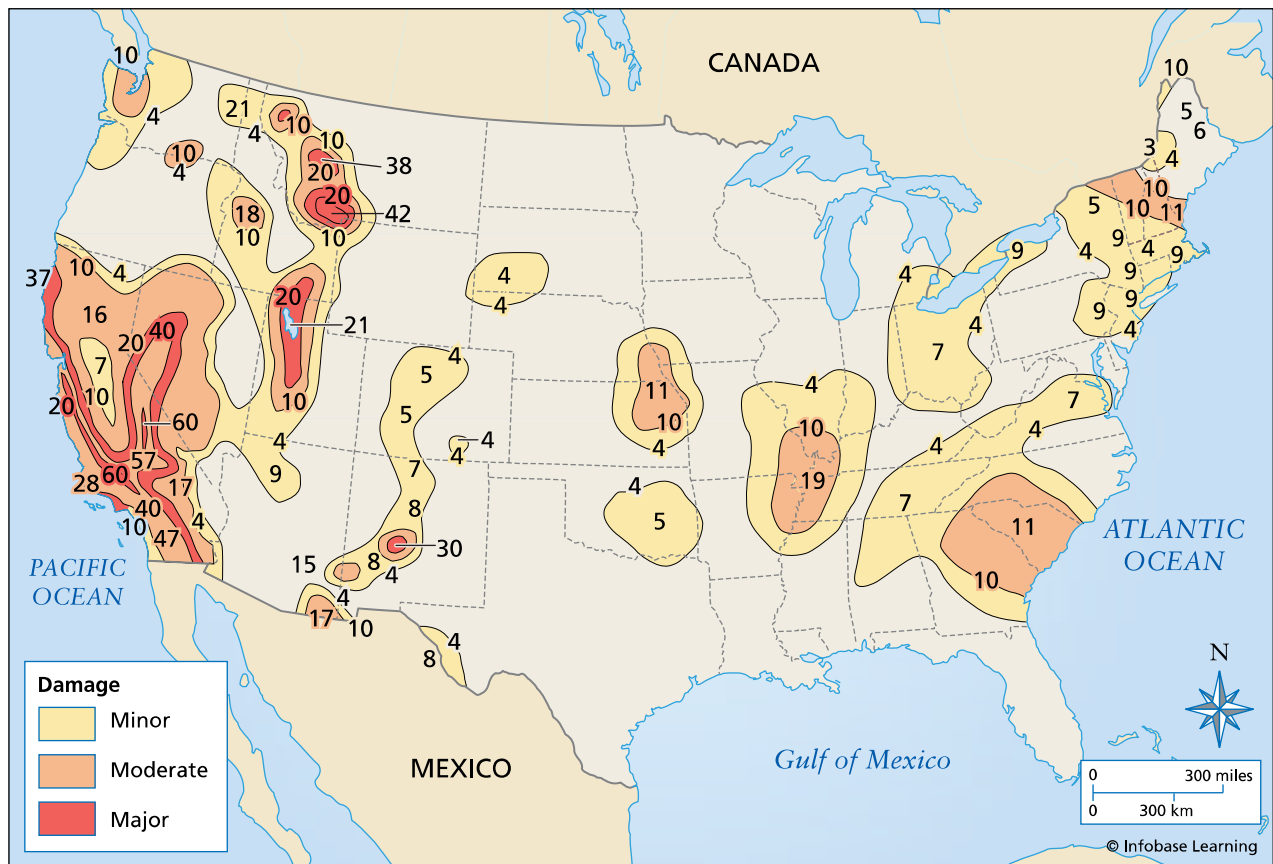

Collapsing buildings during an earthquake also typically raise significant dust. This can be seen under nonearthquake conditions when large build-

ings are demolished for urban renewal. A large dust cloud is typically emitted when they are knocked down or blown up. Considering that old buildings may contain asbestos, lead paint, lead solder, and fiberglass, among other materials, this cloud could well be a health hazard. The dust from both of these sources is typically particulate matter with a diameter of 10 microns or less (PM10), which is considered a respiratory irritant and health hazard.

One of the main dangers of earthquakes in the past was fire. It is still a threat today but not nearly as dire as previously. In historic times, cooking was done on fires, in stoves, or on braziers; lighting was provided by candles and oil lamps; and heating was produced by coal or wood stoves or furnaces. Seismic waves commonly toppled these sources, and the old wood houses of the times were quickly engulfed in flames. As in all earthquakes, buildings tend to topple into the street when they are destroyed. This results in particularly slow going for fire engines and fire brigades. Before modern hydrant systems, horses had to pull tanks of water to the fire, and this small amount of water was dumped on the fire without pressure. In many of the most famous historical

Black smoke from an earthquake-induced fire in Kobe, Japan, 1995 (© Reuters/CORBIS)

**Earthquake risk map for the continental United States with the probability for earthquakes and the expected amount of damage indicated by shading**

earthquakes, the main source of destruction was the fire rather than the seismic waves. In the great Kanto earthquake of 1923 that destroyed Tokyo, Japan, fire was, by far, the most devastating part. More than 142,000 people perished in this disaster, including more than 35,000 at one time in a single sweeping firestorm. These unfortunate souls had survived the seismic waves and had made their way to a military park where a relief area had been erected when the storm struck. There were reports of fire tornadoes because the heat was so intense.

The most famous fire caused by an earthquake in the United States was the one caused by the great San Francisco earthquake of 1906. It basically destroyed the entire city. Fire started in several areas at the same time and spread unchecked until there was no way it could be controlled. The army attempted to bomb a firebreak around the inferno but wound up destroying structures that might have survived, igniting new fires in areas that had been spared the main fire, and causing very unsafe conditions for the survivors. The most striking feature of most photographs of the San Francisco earthquake is the enormous black clouds rising over the city. This

smoke was not only loaded with particulate but with polycyclic aromatic hydrocarbons (PAHs), benzene methylethyl ketone (MEK), and other dangerous chemicals, depending upon what was also burning at the time. This cloud was composed of both PM<sub>10</sub> and PM<sub>2.5</sub> (particulate matter with a diameter of 2.5 microns or less).

### DISRUPTION OF UTILITIES

Both direct surface movement and seismic waves can sever all forms of utilities during a major earthquake. The most obvious problem is the severing of natural gas lines. Gas leaks can occur throughout the affected city and not be stopped until the system is shut down. Methane can cause significant adverse health effects, particularly in the respiratory system, and even lead to death. It is also highly flammable, representing a great risk for explosion. In areas of oil production, this danger is even more pronounced if oil pipelines are severed. Spilled oil can contaminate surface water bodies and other low-lying features such as wetlands, lakes, or ponds and present a fire hazard, as well.

The most reported environmental problem after an earthquake is the cutting of water lines by the shift in ground position. Without a source of fresh water, remaining supplies quickly dwindle and become contaminated with bacteria. Disease that commonly follows major disasters can be directly related to problems with water supplies. This contamination is usually exacerbated by damage to another public utility, sewer lines. They can rupture as easily as the water mains and contaminate any surface water body or low-lying feature. The spilling of untreated sewage can take years to repair. Even well water can be contaminated during earthquakes. Seismic waves typically drive water upward in the soil during earthquakes, resulting in liquefaction, in which soil begins to behave (flow) as a liquid. This vertical movement of groundwater can cause it to become turbid and unpotable as a result of excessive concentrations of silt suspended in it.

### CHEMICAL SPILLS

Any stored chemical is a potential environmental disaster during an earthquake. Cities with oil refin-

eries or chemical industries are particularly vulnerable. Refineries contain enormous amounts of oil stored in large tanks connected by pipelines in various stages of chemical reaction. Refineries are also commonly close to major water bodies, where workers can off-load crude oil from tankers. Serious spills are common at these types of facilities even without an earthquake, and several coastal zones in northeastern New Jersey, near Baton Rouge on the Mississippi River in Louisiana, and near Houston, Texas, are profoundly polluted as a result. Either fortunately or as a result of strictly enforced local building codes, most oil-handling facilities are within seismically quiet regions. If an earthquake were to strike any of these industrial plants, spills from the tank and pipeline ruptures would be catastrophic. These areas also contain major chemical industries that work with refinery products and that maintain large supplies in tanks, which are prone to rupture, as well.

In many cases, the oil industry is aware of the potential damage to pipelines and storage tanks. The huge trans-Alaskan oil pipeline crosses some major active faults with a capacity for surface ruptures. In

**Block diagram of a fault on which an earthquake is taking place: The concentric spheres emanating from the focus illustrate the seismic wave fronts.**

anticipation of potential earthquake activity, facility designers and operators have taken great pains to guard against ruptures of the pipeline, especially in its joints and surface mounts. There are also shutoff valves at regular intervals to halt the flow in the event of emergency. The system was put to the test on November 3, 2002, when a magnitude 7.9 earthquake occurred on the Denali fault, which crosses the pipeline. This earthquake produced a surface rupture 209 miles (335 km) long with up to 29 feet (8.7 m) of lateral offset. Shaking lasted 90 seconds and produced a band of landslides 16–24 miles (9.6–14.5 km) long with fissures large enough to swallow a bus. Under the pipeline, the ground shifted more than 14 feet (4.3 m), and shaking was intense. Yet the pipeline did not rupture, attesting to the excellence of its engineering.

### NUCLEAR POWER PLANTS

Fortunately, no earthquakes have caused a real disaster at a nuclear power plant, although such an event is not out of the realm of possibility. The danger with nuclear power plants is that they require large amounts of water for cooling, and, as such, are commonly located on rivers. The faulting process breaks up rocks, allowing them to be easily removed (eroded) by wind, water, or ice along the fault line, forming a low valley. Rivers follow valleys and, as such, commonly sit on faults. This natural phenomenon has not been unnoticed by the U.S. Nuclear Regulatory Commission, and areas where power plants are proposed undergo a rigorous geological evaluation before a permit is granted. Even after they are operational, close monitoring and reevaluation are common. Thanks to the caution exercised by nuclear power plant owners and government regulators, there has never been an environmental disaster caused by earthquake-induced damage at a nuclear power plant. This, however, may also reflect a certain amount of luck.

The Indian Point nuclear power plant sits on the Hudson River, just north of New York City. It is an old plant, well past its expected life span. Some scientific studies have suggested that the course of the Hudson River is controlled by a covered fault that lies in the base of the river. The power plant is located at the point where the Ramapo fault, perhaps the most prominent fault in New Jersey, crosses the river. The trace of the fault lies right under the power plant. It is believed that the Ramapo fault is active, and there

certainly are numerous small earthquakes along the Hudson River. The largest recent earthquake was in 1884 and was estimated at a 5.2 magnitude, but it was to the south in New York harbor. If an earthquake of magnitude 5.2 or greater occurred under the Indian Point plant, would it cause a meltdown? There are 1.5 million people in the counties around the plant, and the radioactive waste would flow down the river or could be blown by prevailing winds into New York City. It could be the greatest human disaster ever. It is not the only example of a nuclear power plant in a precarious location.

There have been cases when nuclear power plants have suffered damage from earthquakes and even leaks. The most recent incident was the result of a magnitude 6.8 earthquake on July 16, 2007, in Niigata, Japan. The earthquake damaged the Kashiwazaki Kariwa nuclear power plant, which is the largest in the world. It took two hours to extinguish the transformer fires that resulted from shaking, and approximately 315 gallons (1,192 L) of radioactive water spilled into the Sea of Japan. There was no real danger that the plant would go into a catastrophic meltdown, but Japan is capable of much stronger and more damaging earthquakes.

### TSUNAMIS

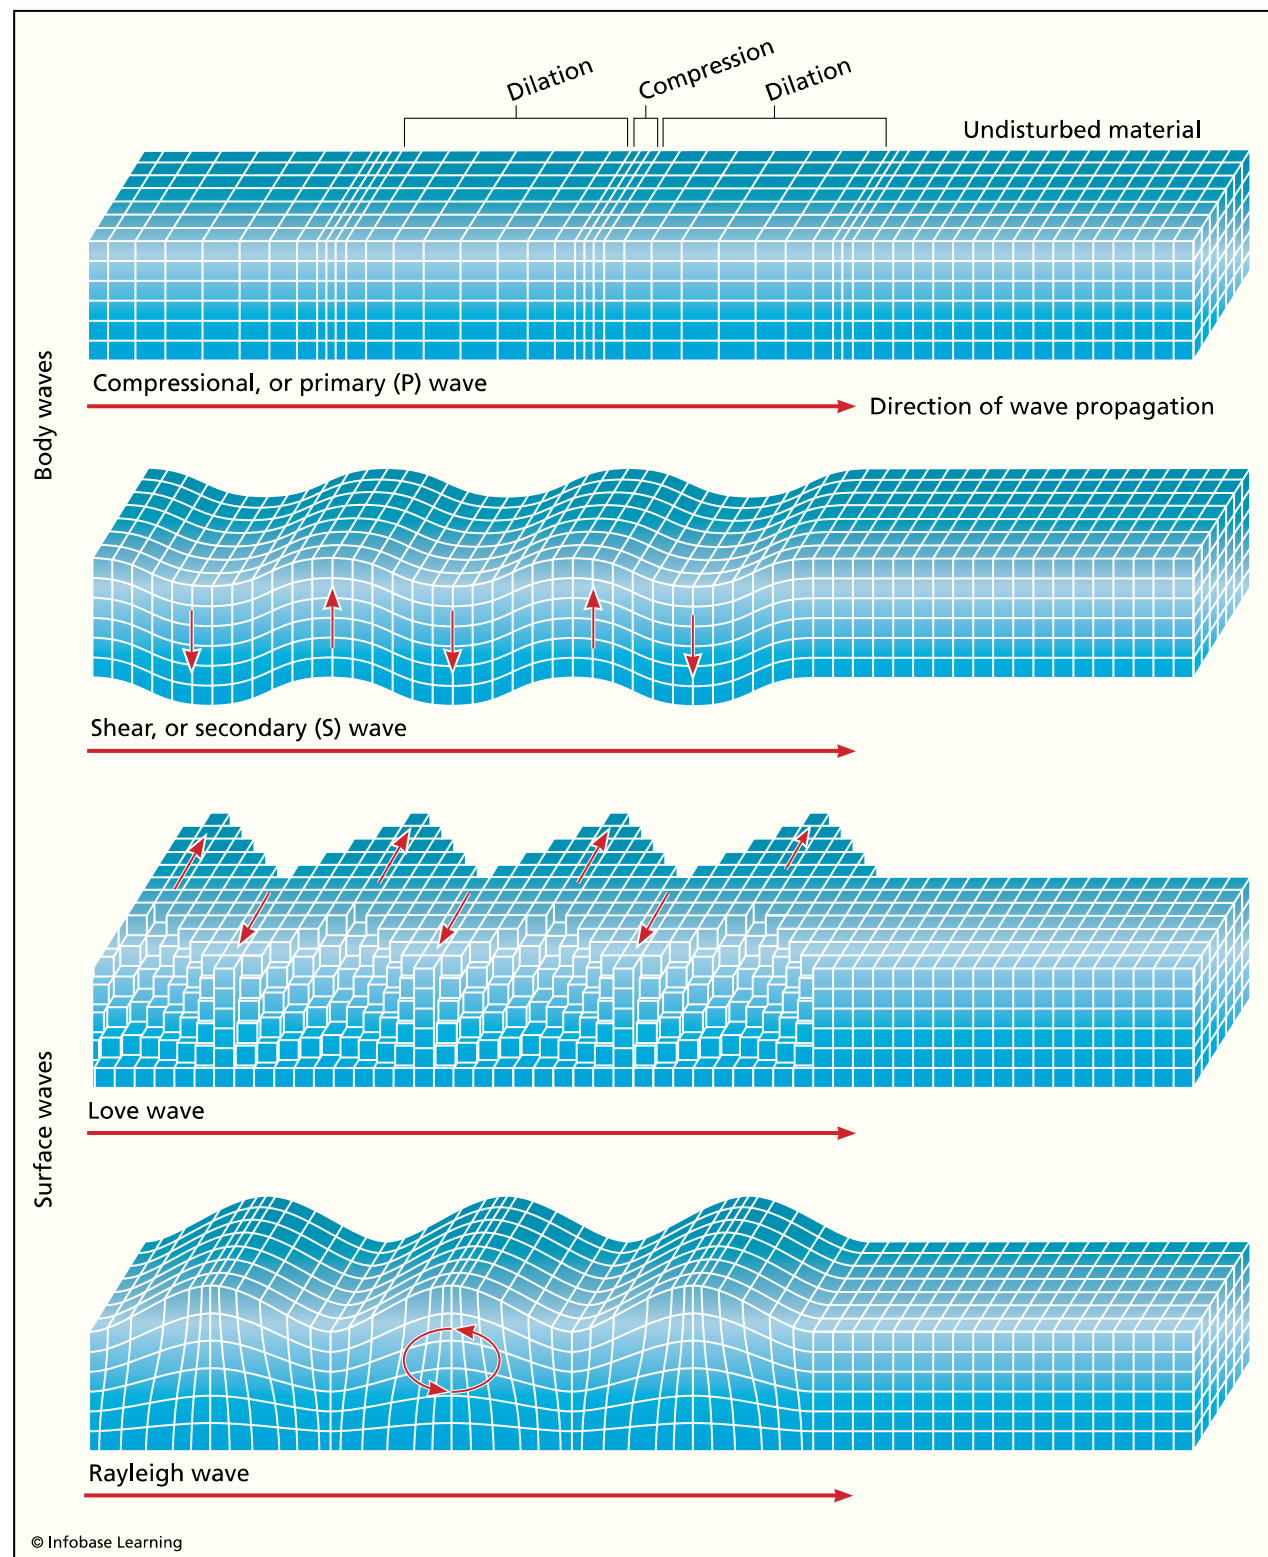

Earthquakes produce a series of life-threatening hazards, the most fearsome of which is a tsunami. If there is uplift of the sea bottom or a submarine landslide occurs, the water column does not react quickly and there may be a temporary “step” on the surface of the ocean. Water tends to seek its own level (remain flat and smooth) and cannot have an abrupt elevation change. A tsunami is the active releveling of sea level. Tsunamis travel at high velocities of 400–700 miles (644–1,127 km) per hour across the open ocean. Although some movies would have people believe that they are huge in the open ocean, this is simply not true. They are no more than three feet (0.9 m) high with a wavelength so long (approximately 328 feet [100 m]) that ships are usually not able to detect them. The word *tsunami* means “harbor wave” in Japanese, because it rises up out of nowhere in a harbor as the wave enters shallow water.

The common perception is that tsunamis are dangerous because they drown people. In reality, although people can drown, too, the real danger is that the waves hit the shore still traveling at 50–60

*(opposite page) Diagrams showing the response of rocks to different types of seismic waves passing through them. The distortion caused by the waves passing through is elastic in that no permanent change in shape takes place. P- and S-waves travel throughout the body of the Earth, but Love and Rayleigh waves only travel along the surface. Surface waves cause the most damage.*

miles (80–97 km) per hour in comparison with the typical wave speed of five to 20 miles (8–32 km) per hour. Depending upon their height, they can crush shoreline structures including chemical tanks and

toss ships, including tankers, onto the shore and rupture them. The massive wall of salt water can penetrate one mile (1.6 km) or more inland, contaminating all surface water and even groundwater

**Block diagram showing the generation of a tsunami through uplift of the seafloor during an earthquake. The uplift causes the overlying seawater to be uplifted as well, and the tsunami is the releveing of the ocean surface. This is by far the most common way tsunamis are generated.**

supplies in the process. The great weight of the water overwhelms all sewer systems, and sewage is pushed to the surface. Debris is strewn everywhere, and decaying corpses of humans and animals spread disease to the survivors. Vegetation is stripped away, and the salt inhibits recovery for years. Environmental damage in Thailand and Indonesia in the wake of the December 26, 2004, Banda Aceh earthquake and tsunami will take many years to overcome, far longer than rebuilding the infrastructure and repopulating the area.

***E. coli*** *E. coli* is short for *Escherichia coli*, a group of bacteria with hundreds of strains. The vast majority of them are harmless. At present, there are four strains of enterovirulent *E. coli* that are known to cause gastroenteritis in humans. These four are designated as the EEC group. The most virulent of this group is the enterohemorrhagic *E. coli* (EHEC) strain, known as *E. coli* 0157:H7. When an outbreak of *E. coli* is reported in the news, it is this strain alone that is responsible for the disease and possible death. *E. coli* is the leading cause of food-borne illness. A 1999 Center for Disease Control and Prevention (CDC) survey found 73,000 cases of infection and 61 deaths in the United States per year, though since then there has been a 29 percent reduction in cases. Although *E. coli* outbreaks result primarily from infected food, they can also affect water supplies. It is for this reason that *E. coli* is considered a pollutant.

#### GROWTH AND OCCURRENCE

*E. coli* occurs naturally in the intestines of healthy cattle, deer, goats, and sheep and can be found on most cattle farms and petting zoos, among other places. It can contaminate the ground, railings, feed bins, and fur of the animals. It can contaminate meat during slaughter and milk that has contact with a cow's udders. It is removed from milk during pasteurization, but it may remain in meat and especially ground beef even after it has been sent to market. *E. coli* cannot be detected on meat and can only be killed if the meat is cooked to a high enough temperature. It can also occur in beans and alfalfa sprouts, lettuce, spinach, salami, and unpasteurized

milk and juice. Even extensive washing may not remove the *E. coli* from contaminated produce, and it requires a very small amount to infect humans. It can also be passed on hands that have been in contact with waste or contaminated foods.

Cattle manure and other animal wastes typically contain abundant *E. coli*. Manure can be a powerful contaminant of the environment. Streams, lakes, and rivers can be contaminated with *E. coli* during precipitation and melting events through runoff. Streams that pass through pastures are commonly contaminated, and irrigation of fields that use manure as a fertilizer can also result in contamination. Sewage spills and overflowing septic systems can also introduce *E. coli* into the environment. Even pools can be contaminated by young swimmers, as well as currently infected older swimmers, for up to 14 days after the symptoms have subsided.

### HEALTH EFFECTS FROM EXPOSURE

Symptoms of *E. coli* appear after two to eight days (average three to four) of exposure to the bacterium. Once inside the human digestive system, it produces large amounts of one or more strong toxins (verotoxin [VT] and shigalike toxins) that are very damaging to the lining of the intestines. The disease that is produced is hemorrhagic colitis, and it is characterized by severe abdominal cramping and diarrhea that becomes bloody in most cases. This condition may be accompanied by vomiting and low-grade fever in some cases. The illness runs its course in five to 10 days, depending upon severity.

In some cases, especially in children less than five years of age and elderly adults, the disease may progress into a severe complication, called hemolytic uremic syndrome (HUS), which occurs in about 8 percent of reported cases of *E. coli*. In this complication, red blood cells are destroyed and the kidneys fail among other symptoms. Some people experience other severe consequences of HUS such as blindness, paralysis, lifelong kidney malfunction, and intermittent failure or complete loss of kidney function. In about 3–5 percent of HUS cases, the result is death. If HUS is accompanied by fever and neurologic symptoms in elderly patients, the condition is called thrombotic thrombocytopenic purpura (TTP), which can have a mortality rate as high as 50 percent.

### REGULATIONS ON HUMAN EXPOSURE

Under the Safe Drinking Water Act, the U.S. Environmental Protection Agency (EPA) limits the total coliforms (including *E. coli*) in drinking water to less than 5 percent with a goal of 0 part per mil-

lion (ppm). They further require the regular testing of public water supplies up to 480 times per month for the largest population served but only once per month for the smallest. Private wells are only tested at the discretion of the owner. Approved systems to disinfect public water supplies include chlorine, ultraviolet radiation, and ozone, all of which will destroy *E. coli*. For individuals to ensure the destruction of *E. coli* in drinking water, they must boil it for at least one minute.

### E. COLI OUTBREAKS

The first identified outbreak of *E. coli* 0157:H7 was in August 1982, when the Centers for Disease Control and Prevention identified 25 cases linked to tainted hamburger meat. The largest outbreak of *E. coli* occurred from November 15, 1992, to February 28, 1993, in the states of Washington, Idaho, California, and Nevada. There were more than 500 laboratory confirmed cases and four deaths associated with this outbreak, and the culprit was, once again, contaminated ground beef. Included in this group were 230 confirmed cases and 80 pending cases of infection from hamburgers consumed at a fast-food restaurant chain in Washington in January 1–29, 1993. Two cases of *E. coli* from contaminated surface water occurred in 1999, when one group of people became sick from drinking water in Washington County, New York, and another group became sick from swimming in contaminated water in Clark County, Washington.

**EDB (1,2-dibromoethane)** 1,2-Dibromoethane (EDB) was very widespread in the United States for many years by virtue of being an additive to leaded fuels. It was emitted from tailpipe exhaust but was banned in the United States after it was found to be highly toxic to mammals, including humans, carcinogenic, and very persistent in the natural environment. However, it is still used in many countries as a gasoline octane booster. For these reasons, and although EDB is present in only 27 of the first 1,416 U.S. Environmental Protection Agency (EPA)–designated Superfund sites where tested, it is still rated number 35 of the 275 compounds on the 2005 CERCLA Priority List of Hazardous Substances. EDB is also known as DBE, alpha- and beta-dibromoethane, dibromoethane, ethylene bromide, glycol bromide, glycol dibromide, and sym-dibromoethane and sold commercially as Bromofume, Celmid, Dibrome, Dowfume, EDB-85, Fumo-Gas, Kopfume, Nephis, and Soilfume. EDB also was commercially used as a pesticide, but this application has also been banned because of the threat it poses to human health and the environment. Now the danger it represents is related to residues in soil and groundwater from prior uses and imported products from countries where it has not been banned.

### PROPERTIES, USE, AND PRODUCTION

EDB is primarily a synthesized substance, but it also occurs naturally in the oceans, where small amounts of it are produced by algae and kelp. It is a halogenated hydrocarbon that had many applications in the past but is sparsely used now. In pure form, EDB is a clear, colorless liquid with a sweet, chloroformlike odor and a tendency to evaporate quickly. The annual production of EDB in the United States peaked at 332 million pounds (151 million kg) in 1974. Its primary use was as an antiknock additive to leaded gasoline. It was used as a scavenger for lead so that it would be removed from the engine after combustion. Even as late as 1978, more than 90 percent of all EDB used in the United States was for this purpose. Leaded fuel, however, was being phased out in the 1970s, and, by 1982, the annual domestic production of EDB was down to 169.8 million pounds (77.2 million kg). The other major use of EDB as a pesticide was as a nematocide for agricultural crops and lawns (especially golf courses) and as a fumigant for a variety of fruit, vegetable, and grain crops (barley, maize, rice, sorghum, rye, oats, and wheat), especially against fruit flies. It also was used to control bark beetles in logs, moths in stored furniture and clothing, termites under concrete slab foundations

and porches, Japanese beetles in ornamental trees, and wax moths in honeycombs. An EPA ban on these uses was enforced in 1984, further reducing the remaining production. Similar legislation in other countries at that time also reduced exports. In 1978, U.S. exports of EDB topped 84.8 million pounds (38.4 million kg), but by 1981 they had declined to 29.8 million pounds (13.5 million kg). By 2000, exports were down to 5.4 million pounds (2.5 million kg). Currently, EDB is used solely in the synthesis of other chemicals and as a solvent for resins, gums, and waxes in the United States.

### ENVIRONMENTAL RELEASE AND FATE

EDB was primarily a nonpoint source pollutant, released from automobile exhaust and pesticide usage. It was and is a point source pollutant through releases from manufacturing, transport, storage, and waste facilities. Vegetation takes up small amounts of EDB from the soil and groundwater, and fumigated food products may contain EDB residues for up to six to 12 weeks. In surface water, EDB mainly evaporates, with an estimated removal half-life of a little more than one day in rivers and five days in lakes. If released into the soil, EDB will degrade by exposure to sunlight or by microbial action and/or evaporate quickly near the soil surface. Once beneath the surface, it is much more persistent, depending upon soil type. It remains in topsoil by tightly binding to organic particles and slowly biodegrading, but it moves quickly out of sandy soils. An estimated removal half-life for field conditions is 100 days, although some studies have found residues persisting for two to as much as 20 years or more, depending upon conditions. Otherwise, about 90 percent of that released slowly leaches into the groundwater system at a proportional rate to temperature (faster at 77°F [25°C] and much slower at 41°F [5°C]) and soil conditions. Once in groundwater, it is even more persistent—for months or years. In one study in New Jersey in 1977–1979, EDB was found in 34 of 421 groundwater samples and 11 of 175 surface water samples.

EDB has mainly been released into the air either by fumigation, evaporation, or automobile exhaust. It breaks down slowly in air by reaction with hydroxyl radicals and photochemical reactions. Removal time is about four to five months, allowing widespread transport in the atmosphere. Both EDB and its breakdown products can cause significant damage to the stratospheric ozone layer. Some studies suggest that these bromine compounds of EDB can be even more efficient than the chlorine-based CFCs (chlorofluorocarbons) in removing ozone.

Industrial release of EDB into the environment was 99,418 pounds (45,190 kg) in 1988 but decreased to 10,054 pounds (4,570 kg) by 1998. By 2005, the industrial release totaled 5,563 pounds (2,259 kg) with a continuous downward trend, with the exception of 1999, in which there was a bad spill.

### HEALTH EFFECTS FROM EXPOSURE

Exposure to EDB typically results in numerous adverse health effects. EDB is considered to be highly toxic (EPA toxicity class I), and acute exposure to it produces rapid breathing, nausea, vomiting, diarrhea, headache, lung damage, clouding of the corneas, blistering of the skin, and, at high dosage, ulcers of the mouth and stomach, liver and kidney damage, and death. Long-term chronic exposure can produce damage to the liver, kidneys, adrenal glands, and testes as well as weight loss, chronic bronchitis, pneumonia, headaches, and depression. It also weakens the immune system of the lungs. Reproductive damage is especially pronounced in males, but EDB can also cause birth defects and delayed brain development and motor coordination in offspring.

The U.S. Department of Health and Human Services classifies EDB as reasonably anticipated to be a human carcinogen, and the International Agency for Research on Cancer classifies it in group 2A, probably carcinogenic to humans. It has been shown to produce numerous types of cancer in laboratory animals including in the nasal cavity, esophagus, alveolar-bronchiolar system, and lungs through inhalation; forestomach, stomach, kidneys, spleen, and liver through ingestion; and in the mammary glands, adrenal cortex, and thyroid glands through any exposure. There is some evidence that EDB is mutagenic in several systems including sister chromatid exchange, mutations, and unscheduled deoxyribonucleic acid (DNA) synthesis, but it has not been shown to cause genetic damage in humans in most studies.

### REGULATIONS ON HUMAN EXPOSURE

As a result of the threat to human health and the environment, exposure of the general public and workers to EDB is regulated by the federal government. The EPA limits EDB in drinking water to a maximum of five parts per billion (ppb) under the Safe Drinking Water Act. They recommend a maximal exposure of 8 ppb for any 10-day period. The Occupational Safety and Health Administration (OSHA) has set a permissible exposure limit (PEL) of 20 parts per million (ppm) of EDB in workplace

air over an eight-hour-day, 40-hour workweek, with a maximal peak level for any five minutes of 50 ppm. The National Institute of Occupational Safety and Health (NIOSH) set their recommended exposure limit (REL) at 45 ppb and their immediately dangerous to life and health (IDLH) limit to 100 ppm in workplace air. The EPA National Occupational Exposure Survey of 1981–1983 estimated that approximately 9,000 American workers were potentially exposed to EDB on a regular basis. Besides the United States, EDB has been banned for agricultural purposes in Egypt, Japan, Kenya, the Netherlands, Sweden, and the United Kingdom, among others.

**Edwards Aquifer** Located in south central Texas, Edwards Aquifer is one of the most productive aquifers in the United States. It is largely a limestone aquifer, which primarily serves the cities of Austin and San Antonio, providing water to more than 2 million people. This important aquifer is unique in its storage capacity, flow characteristics, water producing capability, and efficiency in

recharge (allowing surface water to enter the aquifer). It is for these same reasons that the Edwards Aquifer is very sensitive to pollution and is encountering increased environmental pressures with increased population growth.

### LOCATION AND SIZE

The Edwards Aquifer is contained within the limestone of the Edwards Formation. It is a honeycombed rock unit from extensive karst development that ranges from about 300 to 500 feet (92 to 154 m) thick. The effective area of the aquifer and catchment forms a 160-mile- (256-km-) long arc that extends through 13 Texas counties and ranges in width from five to 40 miles (8–64 km). The total area of the aquifer and catchment is about 8,000 square miles (20,480 km<sup>2</sup>). The aquifer area is divided into three zones, the contributing zone, the recharge zone, and the artesian zone. The contributing zone, or catchment area, is on the Edwards Plateau in the Texas Hill Country and covers about 4,400 square miles (11,264 km<sup>2</sup>). It is from this

high area that the water develops its head, or the pressure that causes it to move through the ground. The recharge zone is south of and downslope from the catchment area and is enhanced by the Balcones fault zone, which has fractured the rocks, allowing quick infiltration of surface water into the underground system. Below and to the south is the artesian zone, where the spectacular flow rates occur. Farther south, the water in the aquifer is saline and not potable. The usable aquifer area is about 3,600 square miles (9,215 km<sup>2</sup>), including 1,250 square miles (3,200 km<sup>2</sup>) of the recharge zone.

### WATER FLOW

The aquifer is recharged mainly by influent streams; a surface water reservoir, called Medina Lake; and even some from the Trinity Aquifer, another groundwater source. In the area where most of the recharge takes place, the Edwards Aquifer contains numerous sinkholes and is unconfined (open to the surface). It behaves as a typical shallow aquifer here, receiving water from surface precipitation and not under artesian pressure or having any appreciable springs. There is a transition area between the recharge and the artesian zone that has some characteristics of each. The artesian zone occurs because the aquifer unit is confined between impermeable layers, thus allowing the steep gradient to increase the water pressure.

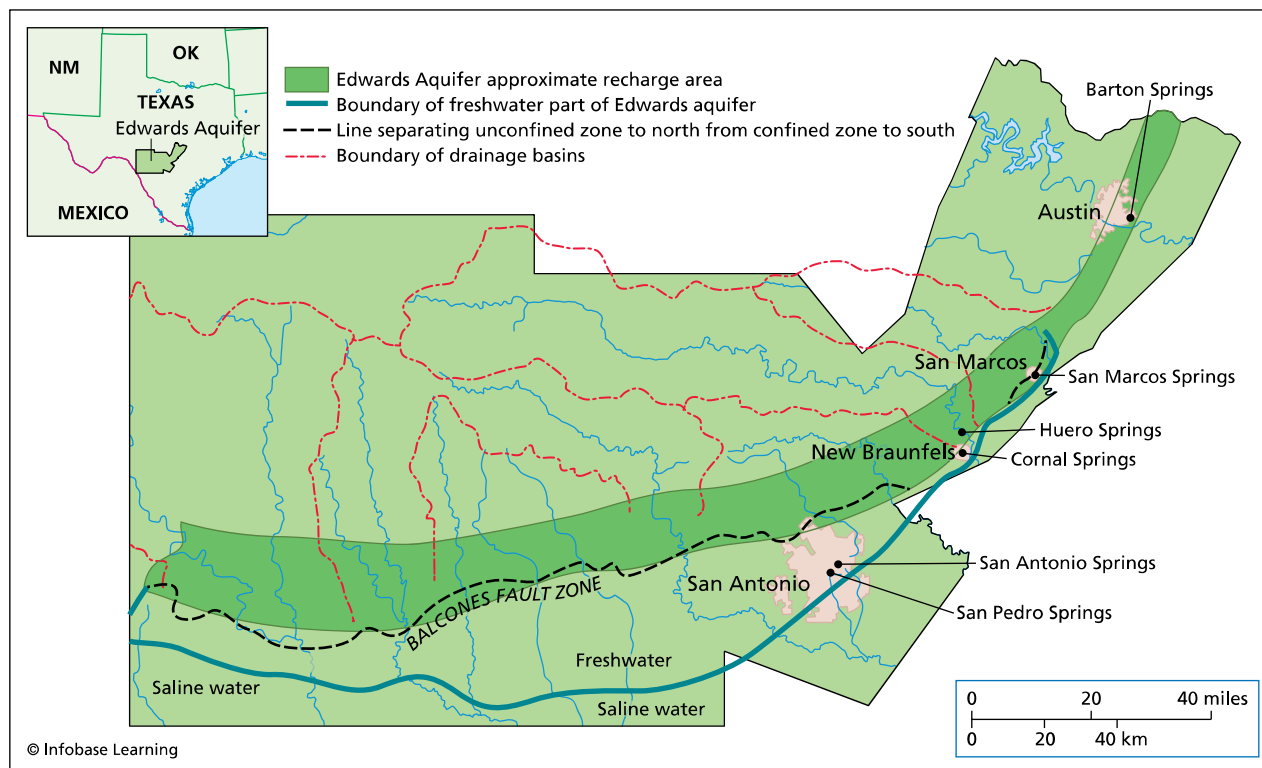

The city of San Antonio began using well water from the Edwards Aquifer for its water needs in 1891. The first well drilled sent a column of water shooting 25 feet (7.7 m) into the air. With such a valuable resource directly underfoot, the Edwards Aquifer quickly became the water supply of choice, and by 1896, there were 40 wells in the city, and the pressure was soon reduced to a trickle. In other areas of Texas, however, it still forms impressive springs in places such as the famous Barton Springs and is still artesian in several isolated spots. In 1991, one of the most productive wells in the world was drilled into Edwards Aquifer. This well yielded about 25,000 gallons (95,000 L) (approximately the size of a large backyard swimming pool) per minute without pumping. This rate is more than enough to supply the needs of most small to midsize towns and cities.

Artesian well in San Antonio, Texas (Peter Essick/Aurora Photos)

### ECOLOGY OF THE SPRINGS

It is the karst features of limestone aquifer that permit the extreme flow rates. Essentially, the water is flowing through caves, and, as such, certain organisms have adapted to live in them. Where the limestone breaches the surface, there is a very open

**Map showing the area served by groundwater from the Edwards Aquifer: Inset map shows the location of the Edwards Aquifer in Texas.**

interaction between surface water and groundwater, with disappearing streams in some areas and spring ponds in others. It is the spring areas of this aquifer that are homes to sensitive ecological communities that include several rare and endangered species, a few of which only occur in the Edwards Aquifer. The organisms emerge from the caves where there is no light, and many are blind or have no eyes at all. Several species include the Texas blind salamander, Helotes mold beetle, the Robber Baron harvestman, and the Robber Baron Cave spider, as well as the fountain darter and the San Marcos salamander. Many of these are endangered and on the verge of extinction.

### POLLUTION AND DEPLETION

As a result of the excessive demand of the burgeoning population in the area, the pressure of the urban/suburban sprawl into areas of aquifer recharge, and the efforts of environmentalists to preserve the water quality and ecology, the Edwards Aquifer has become one of the more prominent legislative battlegrounds in the United States. Recent droughts have threatened the ability of the aquifer to produce enough water to meet demand and raised the question of rationing. In areas of incursion of industry

and development, the quality of the water has suffered with contamination by pesticides, fertilizer, bacteria, and even solvents and heavy metals in the Austin and San Antonio areas. These upstream problems may cause even more severe problems in the downstream areas. The heavy usage can cause the saline water from the Bad Water Zone to be drawn northward into producing wells. The total dissolved solids in this water are about 1,000 parts per million (ppm), far below seawater but still not drinkable. This zone limits any possibility of drilling outside the current aquifer area without extensive desalination efforts. Such activities would also further draw down the already suffering Edwards Aquifer.

**Ekofisk oil field North Sea, Norway April 22, 1977 Water Pollution** Aided by new technologies developed during the cold war, by the 1960s, exploration for oil entered a new level of sophistication. Using such advances as seismic profiling and early data processing techniques, the age of the "wildcat," or the drilling for petroleum hydrocarbons in an area that had not been known for producing oil, was coming to a close. As a result, in the early 1960s, a major new source of oil and natural gas was discovered beneath the North Sea off the coast of Norway. The discovery was in a structure that subsided during the opening of the Atlantic Ocean, called a graben. About 65 million years ago, when the graben formed, it was flooded with sediment rich in organic debris. With time, the organic material in the sandstone and shale that had been buried in the graben was heated and pressurized to form oil and natural gas. These valuable hydrocarbons were trapped in chalk deposits overlying the graben. The oil and gas remained for tens of millions of years, more than one mile (2,900 m) below the seafloor beneath one of the stormiest oceans on the planet, until the late 1970s, when the Ekofisk oil field platforms were brought online and began pumping oil and gas into an undersea pipeline.

Thanks to the Ekofisk oil field, and the other giant North Sea Norwegian oil fields—Brent, Forties, Statfjord, Gullfaks, Heidrun, and Oseberg—Norway emerged as one of the most important non-Organization of Petroleum Exporting Countries (OPEC) (i.e., non-Middle Eastern) sources of oil. In 2002, Norway was the world's third largest net oil exporter and the second largest natural gas provider to Western Europe. Norway's economy is connected closely to its offshore oil and natural gas production, which is its largest source of hard cur-

rency, representing about 18 percent of Norway's gross domestic product. Under international law, Norway owns the continental shelf seabed off its coastline beneath which the oil and natural gas is present. It leases the rights to explore for oil to private companies and charges a royalty for every barrel of oil or cubic foot of gas produced. Although Norway's oil and natural gas are expensive to find and recover because of their great depth below a cold and windy ocean, the oil and natural gas in the North Sea, as well as Norway's political stability and closeness to European markets, allow Norway to enjoy one of the highest per capita income levels in the world.

## BACKGROUND

The Ekofisk oil field is some 200 miles (320 km) east of the Norwegian coastline, and recoverable quantities of oil were first discovered there in 1969. By 1971, Philips Petroleum (now ConocoPhillips) had begun production from a series of interconnected offshore oil platforms where more than 500 people lived and worked. This one-mile- (1.6-km-) long complex included the Hotel Platform, where crew slept, ate, watched the latest movies in a 115-seat theater, visited a chapel, and exercised. Oil and natural gas flowed under their own pressure up through the one-mile- (1.6-km-) deep drilled wells and into pipelines that carried them to processing and refining facilities in Norway or Denmark and, in some cases, the United Kingdom.

In the 1970s, oil prices rose steadily in response to an oil embargo placed on the United States and its Western allies for their support of the 1973 Israeli Yom Kippur War by the Organization of Arab Petroleum Exporting Countries (OAPEC), including Kuwait, Syria, Egypt, Libya, and Saudi Arabia. The embargo also served as a demonstration by both OAPEC and other oil-producing countries that they were in control of their domestic petroleum industries and the pricing of their crude oil. As the flow of oil from the Middle East decreased and as the price rose, the pressure for increased production from the Ekofisk and other North Sea platforms increased. Working around the clock, the men and women staffing the Ekofisk platforms would increase production from 13.7 million cubic feet (0.4 million m<sup>3</sup>) of oil and gas in 1971 to almost 550 million cubic feet (16 million m<sup>3</sup>) by 1977. As more wells were drilled and additional platforms added to handle this increased production, work and safety procedures on the normally very tightly regulated and controlled platforms began to slip.

Norwegian fireboat Seaway Falcon pours water on oil platform “Bravo” in the North Sea, April 24, 1977. (© UPI/CORBIS)

### THE ACCIDENT AND SPILL

On April 22, 1977, one of the 15 production wells on the “Bravo” platform (Bravo 14) at the Ekofisk field was taken off-line for routine maintenance. Prior to taking a well out of service, the operators make sure that its blowout preventer, or BOP, is in place. Oil and natural gas present more than one mile (1.6 km) below the seabed are under tremendous pressure, and to stop their uncontrolled release, called a blowout, special valves or devices are used to seal off or cap the flow of oil or gas in an emergency. On the Bravo platform, each well had two BOPs, one 164 feet (50 m) below the bottom of the seafloor and another at the wellhead, the part of the piping that is connected to the floor of the platform. As the crew performed their “well workover” duties, basically the removal and replacement of gauges and tubing that line the inside of the well, a heavy mud was being pumped into the well to help keep the oil and gas inside the formation. The lower BOP was open to allow the drilling mud to pass through it, and

the surface BOP had been disassembled for repairs. As new gauges were being installed, mud started to bubble out of the well, and, despite the frenzied efforts of the crew to reattach the topside BOP, a blowout occurred and oil and natural gas began to shoot more than 150 feet (45.7 m) into the air at about 175 tons per hour (158,757 kg/h). Fearing a fire or explosion, the 112-person crew quickly abandoned the platform and began emergency response procedures.

Despite the gale-force winds and 15-foot (4.6-m) seas, a firefighting boat stationed at the platform was deployed and began to spray water on the gushing tower of oil to cool and help disperse it and to prevent the buildup of natural gas. Chemical dispersants—whose use was prohibited under the operating agreement between Phillips and Norway—were sprayed around the platform to try to break up the rapidly forming slick.

Within a few hours of the release, platform operators knew they did not have the knowledge or

capability to cap or, “kill,” the out-of-control Bravo 14 well. They turned to the world’s best oil-well fire and blowout control expert, Paul “Red” Adair. Growing up in Texas, Red Adair had been around oil rigs all of his life. During World War II, he served in a bomb disposal unit. Returning to civilian activities, he put his new-found knowledge of explosives to profitable use, devising new ways to extinguish oil-well fires by using explosives to snuff or blow them out. Often after the fire was out, the job of sealing the well and stopping the uncontrolled flow of oil arose. Together with his longtime friend and business associate Asger “Boots” Hanson, Red Adair had helped control such notable fires and blowouts as the 1962 oil-well fire in the Sahara, nicknamed “the devil’s cigarette lighter,” because of flames extending more than 400 feet (121.9 m) from the ground, as well as the Ixtoc I blowout in the Gulf of Mexico in June 1979 and the Piper Alpha fire and spill in July 1988. Perhaps his most notable achievement occurred at the age of 75, when he and his company helped extinguish more than 100 oil-well fires started by Iraqi troops retreating from Kuwait during the 1991 Gulf War.

Boots Hanson arrived within 12 hours of the blowout and started to assemble an all-volunteer team to board the Bravo platform and seal the well. Working conditions were far from ideal: The seas and winds were still very stormy, the noise near the wellhead tremendous, and those working around the well were surrounded by very flammable and explosive levels of oil and natural gas. Joined a few days later by Red Adair, the team, which included members of the company that drilled the well and Philips engineers who operated it, took eight days and five attempts to complete the dangerous work of reinstalling and successfully closing the hardened rubber disks in the topside BOP that would seal the well and shut down the uncontrolled flow of oil. With only a few minor injuries and no loss of life, the Bravo 14 blowout was finally under control. Oil production from the Ekofisk platform resumed four hours later.

### THE CLEANUP

Although the rough seas and strong winds hampered well-closure efforts, they aided in minimizing ecological impacts from the blowout. The type of oil released was fairly low-density liquid, or “light” petroleum, which was pushed out of the wellhead at very high pressures and at temperature close to its boiling point. Several studies estimated that about 50 percent of the oil evaporated before it had contact with the ocean, while the remainder formed a discontinuous slick 45 miles (72.4 km) long by 30 miles (48.3 km) wide,

but only a few tenths of inches thick. The blowout is thought to have released a total of 30,000–60,000 tons (7.5 million–15 million gallons, or 28.4 million–56.8 million L) of oil over an eight-day period. Although mechanical skimmers were in use constantly almost immediately after the blowout occurred, the rough seas and lack of experienced operators limited their effectiveness, and they collected only about 800 tons (200,000 gallons, or 757,000 L) of oil, a very small fraction of that which was released. Wave and wind action, as well as the water spray from the fire vessel that was deluging the Bravo platform, served to mix and emulsify the oil, causing it either to dissolve in the sea or to congeal and sink to the bottom. These same winds also blew the slick away from the Norwegian coastline and out into the open ocean. By May 9, 18 days after the blowout, no visible evidence of an oil slick could be found.

### THE AFTERMATH

Ecological impacts from the blowout were not apparent. Later studies found no damage to fish, larvae, seabirds, or other marine life. Evidence for this and other releases tends to confirm the general oil industry consensus that the most severe environmental effects are those that occur when oil is released close to land, where it can wash onto beaches, or into sensitive habitats such as estuaries or nesting/spawning grounds. Ocean oil spills are readily processed by the natural dispersion, attenuation, and biodegradation mechanisms that operate in the vastness of the open seas.

An investigation of the spill by the Norwegian government, including the police, who looked at possibly filing criminal negligence charges against the well operators, found that workers had failed to follow required procedures and did not notice several unusual indications of potential wellhead problems. Mud had begun leaking out of valves and tubing at the top of the well, and the topside BOP had been disassembled and was lying in two pieces on different levels of the platform. When the crew quickly tried to reattach it to the wellhead, they installed it upside down. The deeper, down-hole BOP had not been locked into place correctly, and it was later found lying relatively intact on the platform, blown out of the well from more than 100 feet (30.5 m) below the seafloor. The financial losses associated with the Bravo blowout totaled approximately \$200 million, with more than half (about 65 percent) lost royalties and taxes that should have gone to the people of Norway.

North Sea oil production peaked in 1999 and has been declining at an annual rate of about 3

percent per year. Ekofisk is expected to continue to produce economic quantities of oil until 2050. Even though improved operational and training procedures have prevented other major blowouts at Ekofisk, the oil field recently faced the new problem of subsidence. As the oil was removed from within the fractures and breaks in the rock, they began to recrystallize and seal, with a resulting loss of overall volume. As more oil was removed, the seabed upon which the oil platforms rested began to sink, in some places by almost 10 feet (3.1 m). This subsidence obviously represented a major threat to the structural integrity of the oil platforms and could not be allowed to continue. The solution developed to address this problem included the reinjection of water into the wells as the oil was drawn out. This not only reduced the subsidence but also had the added benefit of increasing oil recovery rates as the injected water helped flush oil from the fractures and joints of the rock.

**Endicott solvent contamination**  
**Endicott, New York 1979-present Water Pollution** The Village of Endicott, a subdivision of the town of Union, New York, about 185 miles (298 km) northwest of New York City, proudly proclaimed itself as the "Birthplace of IBM." In 1888, Herman Hollerith, a statistician, founded the Tabulating Machine Company in Endicott, attracted to the village by its machine shops, a reliable supply of clean water from the nearby Susquehanna River, and the

industrial infrastructure in the area. Once established in a small two-story brick building, Hollerith won his first contract with the U.S. Census Bureau and used a machine of his own creation to process population and demographic information from the 1900 census on small cards with tiny holes punched through them.

By 1911, the company had merged with two others to form the Computer Tabulating and Recording Corporation (CT&R) and was processing freight bills for the railroads, claim information for insurance companies, and personnel data for the military. Never selling its equipment, CT&R began to build and lease card-punch and card-reading machines to customers. In 1924, just a few years before its founder's death, the company was renamed International Business Machines Corporation, or IBM. Today, with more than 300,000 employees, IBM is the world's second largest computer company, manufacturing and selling computer hardware, software, and consulting services that include everything from large mainframe systems to research on nanotechnology.

#### THE POLLUTION INCIDENT

As IBM grew, so did its need for local industrial manufacturing space. By the late 1970s, it operated on 40 acres (57 ha) in 30 separate and interconnected buildings within Endicott and was one of the area's major employers. IBM also ran other production facilities in nearby Fishkill and Beacon, New York. The company's manufacturing activities involved the use of a wide variety of industrial solvents, which were not always carefully handled or managed. In 1979, an employee accidentally released 4,000 gallons (15,000 L) of 1,1,1-trichloroethylene (TCA). IBM moved quickly to clean up the spill, but subsequent soil and groundwater investigations found a large plume of contamination that indicated apparent ongoing chemical releases over a long period. In addition to 1,1,1-TCA, environmental hydrogeologists retained by IBM and the New York Department of Environmental Conservation (DEC) found trichloroethene (TCE), tetrachloroethene (PCE), methylene chloride, Freon, benzene, and other solvents in groundwater not only beneath the IBM Endicott property but also underlying nearby residential and commercial areas.

#### THE CLEANUP

To address the groundwater contamination, IBM instituted a series of corrective measures as part of its Resource Conservation and Recovery Act

IBM headquarters in Endicott, New York, ca. 1937 (@ Lake County Museum/CORBIS)

(RCRA) hazardous waste permit. Over the next 25 years, IBM installed and operated an extensive groundwater recovery program to capture and treat the contamination that had been released from its North Street facility.

When groundwater is withdrawn from an aquifer, or water-bearing zone, by a pump installed in a well, it causes a “cone of depression” in the water table whose shape is dependent on such factors as pumping rate, or the amount of groundwater being withdrawn over time; the amount of water the subsurface sediments hold; and the rate at which new groundwater can move through the subsurface to replace the groundwater that has been pumped out. When viewed from the surface, the cone of depression extends outward from the well to form a roughly circular zone, called an area of influence. When wells are aligned in a pattern such that their cones of depression overlap, they create an obstruction or barricade through which groundwater cannot move. This remedial approach is called pump and treat, a system of wells aligned to form a subsurface hydraulic barrier so as to collect contaminated groundwater for subsequent treatment and prevent its migration to uncontaminated areas. Treated water is discharged to the local storm or sanitary sewer or sometimes is pumped back into the ground to try to flush remaining contaminants out of the soil.

By 2005, IBM had drilled and sampled more than 220 monitoring wells and was recovering water from 17 extraction, or pumping, wells at its plant site and at various locations throughout the village of Endicott. This water was treated by passing it through an air stripper to force the volatile organic contaminants out of solution and then through a granulated activated carbon (GAC) recovery unit.

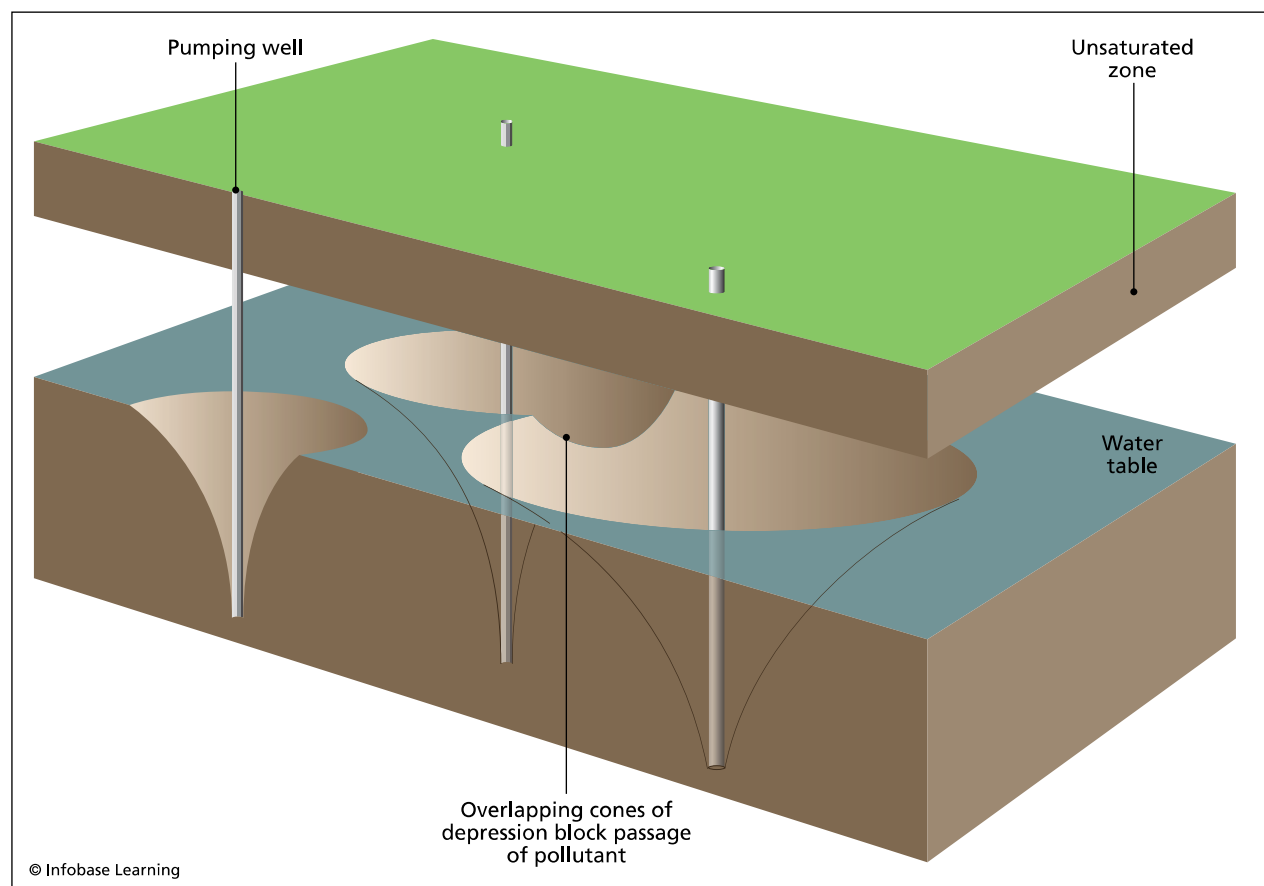

The local hydrogeology complicated IBM’s remedial efforts. Five distinct geologic units underlie the village, and groundwater is present in at least two aquifer systems. At the surface, there are a layer of unconsolidated alluvium of silt, sand, and gravel washed up onto the site as the Susquehanna River carved out the valley, as well as fill composed of various types of soil and debris placed throughout the village to raise sections of it up to a usable grade. Groundwater is present in this layer and only a few feet below the surface. Underlying the alluvium and fill is an extensive layer of lake-deposited silt intermixed with glacially derived, silty fine sand. This layer is relatively impermeable and acts as an aquitard, or a type of geologic unit that tends to slow the vertical movement of contaminants that have been released into the alluvium and fill. Below the silt and silty sand is a layer of coarse-grained sand and gravel, formed and deposited by glacial meltwater. These deposits together with the deeper shale bed-

rock compose the main aquifer in the area and serve as the primary source of drinking water for Endicott and Union. Commonly present on top of the shale bedrock and underneath the glacial outwash deposits is an intermediate layer of dense, consolidated glacial till made up of clay, silt, sand, and gravel. All five of these units vary in thickness and may not even be present, depending upon how the river and glaciers moved across the area.

The majority of the IBM-operated extraction or pumping wells have been drawing water from the alluvium and fill, for it is in this geologic layer that most of the chemical releases occurred. Some contamination has been detected in the deeper aquifer, however, and IBM has installed and is operating groundwater recovery wells that also tap this water-bearing zone. Additionally, IBM has paid for the installation of a special water treatment system on a municipal well; this well extracts groundwater from the outwash and bedrock aquifers.

On average, about 6,000 pounds (2,700 kg) of volatile organic chemicals are recovered every year

from the more than 150 million gallons (568 million L) of groundwater pumped from beneath the village and IBM plant. This water is sampled and then discharged to local storm sewers in accordance with a variety of New York State discharge permits held by IBM. As might be expected, the highest levels of subsurface contamination are present near the IBM plant, but the TCE and other solvents making up the contaminant plume have moved with local groundwater flow patterns and migrated southward off the IBM property and toward the Susquehanna River. Although pollutants have been detected in groundwater samples from both the shallow and deep water bearing zones, it is clearly the near-surface aquifer that has been most affected. The village's water supply system has been adequately protected by the actions taken by IBM and NYSDEC. The volatile organic compound (VOC) pollutants in the groundwater present the health risk of vapor intrusion into basements of those homes and buildings it has migrated beneath.

**Overlapping cones of depression from pumping wells effectively form a barrier against the migration of light non-aqueous phase liquid (LNAPL) pollutants in an area. LNAPLs float on top of the water table and are drawn off in the well. The water can then be treated in an ex situ remediation system.**

### A NEW THREAT, VAPOR INTRUSION

As the dissolved chemicals in the groundwater move through the subsurface, they encounter features and conditions that reduce their ability to remain in solution. The types of chemicals released at the IBM site readily evaporate. VOCs such as benzene or toluene, which are the principal constituents of gasoline, evaporate readily. When the contaminant is dissolved in and moving with groundwater and flows underneath buildings, VOC vapors may push up through the soil and enter the overlying structures, following outside pipe ways, or seeping through cracks in building foundations or floor slabs. This process, called vapor intrusion, may result in the accumulation of unhealthy levels of VOCs inside buildings and expose building occupants to adverse health effects through the inhalation of those compounds.

The potential health impacts from soil vapor intrusion first attracted widespread attention in the environmental and regulatory community in the late 1990s and early 2000s as a result of a study conducted in Redfield, Colorado. Although the magnitude of the public health issues surrounding this phenomenon is still being quantified, USEPA, NYSDOH, NYSDEC and IBM took aggressive action to assess and remedy places at Endicott where it may have occurred.

In 2001, a series of studies began to determine whether VOC vapors had migrated into homes and businesses above the contaminant plume and, if they had, how much was present. In study areas to the southwest (downgradient) of the IBM property, PCE and TCE were found in indoor air at concentrations between 0.1 to 140 mcg/m<sup>3</sup>. Soil gas samples taken from below building floor slabs and in areas adjacent to homes contained much higher TCE values, greater than 10,000 mcg/m<sup>3</sup>, and PCE, another organic solvent, but one not used by IBM, was found in indoor air samples at above 20 mcg/m<sup>3</sup>. NYSDOH has established exposure guidelines for PCE of 100 mcg/m<sup>3</sup> and for TCE of 5 mcg/m<sup>3</sup>. Although the possibility of serious health effects related to the concentrations of PCE and TCE found in air samples from the tested homes is low, the presence of much higher values in soil gas samples made it prudent to conduct mitigative actions.

PCE, which has not been tied to releases from IBM, is present in some types of spot removers and is used in dry cleaning. Other types of businesses also use these chemicals including auto body repair shops, printers, and metalworking facilities. The source of the PCE found in soil gas at Endicott has not been determined, but NYSDEC suspects that

it may have originated from several dry cleaners in the area.

Soil gas venting systems consist of a series of perforated pipes driven or drilled into the soil adjacent to a building, or even through the floor slab of a basement. A flexible hose or rigid plastic tube is attached to the end of each pipe and connected to a vacuum pump that continually draws air from the subsurface and out a central stack or vent usually installed on the roof, where it is safely dissipated into the atmosphere. Diverting the soil gas into the vapor extraction system greatly reduces or minimizes the likelihood that PCE or TCE will enter the building. These types of systems were installed in almost 500 Endicott businesses and homes.

Both NYSDOH and IBM have repeatedly stated that concentrations of TCE found in indoor air contaminants are well below those that cause negative health impacts; however, some residents are concerned that illnesses and cancers are related to them. Many are considering legal action against IBM. Two studies done in 1986 and 1995 by NYSDOH, however, concluded that there has been no increase or decrease in cancer occurrence since the contamination was first reported. Studies about the possible effects of TCE in indoor air on residents' health are ongoing.

IBM has offered to compensate property owners who have had a ventilation system installed with a one-time payment of \$10,000, or 8 percent of the full market value of their property, whichever amount is larger. If the owner accepts the money, however, he or she cannot file a claim against IBM for property damage in the future. Property owners would still be able to pursue personal injury or other claims associated with the contamination.

**endosulfan** Even though endosulfan is present in only 17 of the first 1,177 U.S. Environmental Protection Agency (EPA)–designated Superfund sites, it is still rated 54th of the 275 compounds on the 2007 CERCLA Priority List of Hazardous Substances, and endosulfan sulfate, which is a breakdown product of endosulfan, is rated 55th. The reason for the high rating is that endosulfan is a highly toxic restricted use pesticide (RUP) as of 1991 that is considered to be in the EPA toxicity class Ib (highly hazardous). It may not be present in many hazardous landfills, but because it is so widely distributed and so toxic, it is regarded as an extreme environmental threat. It was even involved in a major poisoning incident in Kerala, India, in 2001. Endosulfan is also known as Afidan, Benzoepin, Beosit, Cyclodan, Devisulfan, Endocel, Endocide, Endosol, FMC 5462, Hexasulfan, Hildan, Hoe 2671, Insectophene, Malix, Phaser, Thiodan, Thimul, Thifor, and Thionex, among others (94 products in total).

### PROPERTIES, USES, AND PRODUCTION

Endosulfan is a chlorinated hydrocarbon of the cyclodiene subgroup that is used as an insecticide and an acaricide. Endosulfan occurs as colorless to yellow-tan sugary crystals and is typically a mix of two forms, the alpha- and beta-isomers. It is commercially available as an emulsifiable concentrate, wettable powder, ultra-low-volume (ULV) liquid, and smoke tablets. It is primarily applied to crops such as tea, coffee, cotton, oilseed, fruits, and vegetables (squash, eggplant, cantaloupe, sweet potatoes, broccoli, lettuce, pears, pumpkins, tomatoes, melons, apples, strawberries, grapes, blueberries, and many others), as well as to rice, cereals, maize, sorghum and other grains and to Christmas trees and ornamental shrubs, trees, and vines. It has also been used as a wood preservative. Endosulfan was registered as a pesticide in the United States in 1954. The annual domestic use of endosulfan is estimated at 1.38–2.2 million pounds (627,272–1 million kg)

of active ingredient, but it is always used in a diluted form of 9–50 percent.

### ENVIRONMENTAL RELEASE AND FATE

Endosulfan is primarily released in agricultural applications as a nonpoint source pollutant and far less often as a point source pollutant from improper handling or spills and leaks during manufacture, transport, or storage. It is primarily released into the soil, where much of it evaporates and the rest enters and adheres to clay and organic particles. Endosulfan is moderately persistent in soils, with an average removal half-life of 50 days, although it is reported that the half-life for the alpha-isomer is 35 days and that the beta-isomer is 150 days. It has been shown to persist longer under acidic conditions. In sandy loam soil, it has been shown to have a removal half-life up to 800 days. Endosulfan breaks down to endosulfan sulfate, which is even more persistent and still toxic. In one study, after 11 weeks, 90 percent of the residue remained. Breakdown is primarily through biodegradation, though minor chemical reactions also contribute. Some endosulfan leaches into the groundwater and has been found in wells in California, but this occurrence is rare. It is more commonly washed into surface waters from runoff over agricultural fields. It does not dissolve well in water so is mainly carried along attached to particles until it settles into the bottom sediments and persists similarly to the way it persists in soil. The dissolved endosulfan either evaporates or breaks down relatively quickly, depending upon conditions (one day to two months). Strongly alkaline conditions promote faster degradation than neutral or acidic. Endosulfan can travel long distances in air before settling to the ground or breaking down through photochemical reactions.

Endosulfan is highly toxic to fish, birds, bees, aquatic organisms, and many insects, although not to some beneficial insects such as parasitic wasps and ladybugs. It has had 91 poisoning incidents reported on the EPA Ecological Incident Information System (EIIS), which accounts for 62 percent of all incidents since 1971. Endosulfan can bioconcentrate significantly in some organisms such as mussels, where it accumulates up to 600 times the ambient water levels.

### HEALTH EFFECTS FROM EXPOSURE

Endosulfan has been shown to produce numerous serious health effects through both acute and chronic exposure. Acute exposure has produced adverse effects on the central nervous system and gastrointestinal

tract including hyperactivity, hypersensitivity to light and noise, muscle tremors, salivation, loss of coordination, gagging, vomiting, diarrhea, agitation, possible temporary blindness, periodic and continuous convulsions, loss of consciousness, and death at a high enough dose. Long-term chronic exposure produces damage to the liver, kidneys, blood chemistry, parathyroid gland, and immune system. It has also been shown to damage the reproductive organs and cause skeletal deformities in fetuses. Endosulfan does not appear to be carcinogenic, but it is so toxic that the mortality rate of the laboratory animals was very high during experiments. More tests may be needed to verify its potential as a carcinogen. It has been shown to be mutagenic to cells in laboratory tests, a finding that may suggest the ability to induce cancer.

### REGULATIONS ON HUMAN EXPOSURE

As a result of the extreme toxicity, several federal agencies have regulated human exposure to endosulfan. Besides the restrictions imposed by the RUP status, the EPA recommends a limit of 74 parts per billion (ppb) of endosulfan in water from lakes and rivers and 0.1–2 parts per million (ppm) on the surfaces of agricultural products. They are currently considering additional restrictions. The Occupational Safety and Health Administration (OSHA) has set a permissible exposure limit (PEL) of 0.1 milligram of endosulfan per cubic meter of workplace air over an eight-hour-day, 40-hour workweek. Endosulfan has been banned in at least 80 countries and severely restricted in 12 others.

**endrin** There are numerous toxic pollutants. The only people poisoned by the vast majority of them are careless or uninformed industry workers or those who wish to take their own lives. This is not the case with the pesticide endrin, which is responsible for the poisoning of several groups of people around the world. Perhaps the most famous incident is the 1967 death of 26 Saudi Arabians and hospitalization of 874 others that resulted from endrin residues in bread. It was for this serious public health threat that the Environmental Protection Agency (EPA) severely restricted its use in 1979 and finally banned it altogether in 1991. Even after all of this time, endrin is still rated number 41 on the 2007 CERCLA Priority List of Hazardous Substances, which includes 275 entries. It has been identified in 120 of the first 1,428 U.S. Environmental Protection Agency (EPA)–designated Superfund sites, and its metabolite endrin epoxide has been identified in 37 Superfund sites (National Priorities List). The pesticide endrin is also known as Nendrin, EN 57, Endrex, Endricol, Hexadrin, Mendrin, Oktanex, and Compound 269.

### PROPERTIES, USE, AND PRODUCTION

Endrin is an aliphatic organochloride (organic carbon and chlorine atoms bonded together) and a cyclodiene pesticide (carbon bonded to a chlorinated methylene group) that does not occur naturally. It is closely related both chemically and structurally to aldrin and dieldrin. Endrin is a sugary solid that is colorless, white, or tan and has a faint chemical odor. It was primarily used as an insecticide but also in control of rodents and birds. As an insecticide, about 80 percent was used on cotton with additional applications to other field crops such as maize, sugarcane, rice, wheat and cereals, and tobacco in Australia. It was also used on ornamental shrubs and trees, and sugar beets, as seed treatment, and as a cutworm treatment for corn and potatoes. Endrin has been used to control rodents (mainly mice and voles) in orchards, unwanted bird species

on buildings and other structures, and grasshoppers in noncroplands. Endrin was first used in the United States in 1951. Production peaked in 1961 at 10 million pounds (4.5 million kg), but after news of the poisoning incidents emerged, it decreased to 1 million pounds (454,545 kg) by 1971. Production declined to 100,000 pounds (45,545 kg) in 1980 immediately after the first restriction in 1979 and was completely terminated even before the second restriction in 1991.

### ENVIRONMENTAL RELEASE AND FATE

As with most other pesticides, almost all endrin that was produced was released to the environment as a nonpoint source pollutant. The only point source pollution results from improper disposal and leaks and spills from production, transport, and storage. Endrin is almost exclusively released to soil and very little evaporates. Instead, it adheres tightly to organic and clay material within the soil and remains fixed for potentially long periods. One study found that after 14 years of degradation, 41 percent of the original endrin remained in the soil. This means that endrin applied many years ago may still be a threat to those who may have contact with it today. Another study, however, found small quantities of endrin in groundwater, an indication that under certain conditions, it may not be as tightly fixed in the environment and leach deeper into the soil. As recently as 1996, endrin was found in significant quantities in soils in California, Alabama, Georgia, Illinois, Arkansas, Louisiana, New York, New Jersey, Nebraska, North Carolina, and Florida. Endrin slowly degrades through chemical reactions and microbial activity under anaerobic conditions. Runoff over agricultural areas carries it into surface water. Once there, endrin attaches itself to particulate matter and settles into the bottom sediments, where it is also quite persistent. Endrin has entered the atmosphere where it has been sprayed but primarily attaches itself to dust and other particulates and returns to the surface by fallout or washout during precipitation events.

Endrin is devastating to the ecology of an area. It is highly toxic to fish, birds, small animals, aquatic invertebrates, bees, and other insects. There is high bioconcentration of endrin in fish and snails, with factors of 1,335–10,000 and up to 49,000 times ambient levels, respectively. Endrin is also taken up by roots and distributed throughout the leaves of many plants, making it an effective pesticide. In studies on tobacco plants, the rate of uptake was 32–47 percent. Cotton plants were found to distribute the endrin to their leaves, where 60 to 80 percent

evaporated within six to 18 weeks. This indicates that endrin residues may persist for a long time.

### HEALTH EFFECTS FROM EXPOSURE

Endrin is a strong poison that produces dangerous health effects. With acute exposure, it can irritate the skin and eyes and even damage vision. It causes nausea, vomiting, diarrhea, loss of appetite, profuse sweating, muscle weakness, headaches, confusion, dizziness, and muscle tremors. At high dosage, it causes periodic to continuous seizures, unconsciousness, coma, and death relatively quickly. It may take many weeks for the acute symptoms to subside. Long-term, chronic exposure of laboratory animals to endrin produces irritability, depression, anxiety, numbness, weakness in the hands and feet, and liver damage at low doses and damage to the brain, liver, kidneys, and adrenal glands at high doses. There are no definitive studies linking endrin exposure to increased incidence of cancer, and it is not currently considered to be a carcinogen.

### REGULATION OF HUMAN EXPOSURE

Besides the bans, public and worker exposure to endrin is regulated by several federal agencies. The EPA limits endrin in drinking water to a maximum of two parts per billion (ppb) under the Safe Drinking Water Act. They recommend a maximal exposure of 20 ppb for any 10-day period for adults and one-day period for children, but for any longer periods it should not exceed 3 ppb for children or 10 ppb for adults. The Occupational Safety and Health Administration (OSHA) set a permissible exposure limit (PEL) of 0.1 milligram of endrin per cubic meter of workplace air over an eight-hour-day, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) has set their recommended exposure limit (REL) as the same as OSHA's but over a 10-hour day. They have further set their immediately dangerous to life and health (IDLH) limit to 2 milligrams of endrin per cubic meter of workplace air, which is very low. Endrin has been banned in only seven countries including the United States. This means that imported food from many countries may still contain endrin residues.

**Ensign Bickford Simsbury, Connecticut 1997 Soil Pollution** Since 1836, Ensign Bickford Company of Simsbury, Connecticut, which is now owned by Dyno Nobel, has been developing and testing explosive products at its 350-acre (142-ha) facility, 15 miles (24 km) northwest of Hartford. The property is divided into two sections: a 200-acre (81-ha) western parcel, which is heavily wooded and contains numerous bunkers used for the storage of raw materials and finished goods, along with several process buildings; and a 150-acre (61-ha) eastern operational area where the majority of manufacturing and waste management activities have taken place.

### CONTAMINATION OF THE SITE

During manufacturing, blasting agents, pyrotechnics, primers, and boosters were developed and tested in a three-acre area of the eastern parcel called the Open Burn/Open Detonation (OB/OD) area. This type of open-air testing was standard industry practice, but is no longer done as more sophisticated computer modeling and laboratory testing techniques have replaced "fire-in-the-hole" approaches. As have many industrial activities, open-air detonation of explosives left an environmental legacy that had to be addressed. Soil at the OB/OD area is a silty loam with a pH in the range of 6.5–7.5. The water table is relatively shallow (two to four feet, or 0.6 to 1.2 m, below surface), and site drainage is poor, with portions of the property remaining saturated

throughout most of the growing season from April to October. In fact, most of the OB/OD area is within the 100-year floodplain of the nearby Farmington River. Inside the OB/OD area, the soil contains lead with an average concentration of 635 mg/kg to more than 4,000 mg/kg in a few places. Most regulatory agencies consider lead concentrations in soil safe for residential uses if they are at 100 mg/kg or less. Working proactively with the U.S. Environmental Protection Agency (EPA) and Connecticut Department of Environmental Protection (CTDEP), Ensign Bickford funded a phytoremediation project on a 2.4-acre (1-ha) tract of the OB/OD area to address this soil contamination.

### REMEDICATION OF THE SITE

Plants are very adept at extracting water from soil. The remedial practice of phytoremediation, also known as phytoaccumulation or phytoabsorption, takes advantage of this capability and occurs when

Mustard flower (*Brassica juncea*), often used in phytoremediation, in blossom (Joellen L Armstrong; used under license from Shutterstock, Inc.)

soluble contaminants, including metals and radionuclides, are taken up by the roots and concentrated in the aboveground portion of the plant. The contaminants are not altered or degraded, merely relocated to the leaf or stem. The plant then is harvested and disposed of in an appropriate manner, usually by incineration, or the metals can be chemically extracted from the plant for recycling.

Although heavy metals are generally phytotoxic, some plants, known as hyperaccumulators, have developed on metal-rich soils and can tolerate concentrations 100–1,000 times higher than less resistant types can. Hyperaccumulators generally are considered to be plants that have a ratio greater than 1 for concentrations of metals in the roots compared to the leaf and stem. Phytoextraction occurs in the upper portion of the root zone, which in most plants is the top two feet (0.7 m) or so of the soil column, which is relatively shallow. This may be a limiting factor in the application of phytoextraction as a broadly used remedial technique, although deep tilling has been effective in moving soil from six to eight feet (2 to 2.7 m) below the surface to within two feet (0.7 m) of grade, well within the root zone of most plants.

Another factor limiting the use of phytoextraction is the sorption, or attachment, of metals onto soil particles. Clay particles in soil are negatively charged, whereas most inorganic metal ions are positively charged. This causes the inorganic metals to sorb, or attach themselves, to the surface of the clay particles. To keep the metals available to the plants, a chelating agent can be added to the soil. A chelator is an organic compound that bonds with and removes free metal ions from solutions. Ethylenediaminetetraacetic acid (EDTA) is a synthetic amino acid that is particularly effective at this. EDTA, which is most commonly used in the treatment of lead poisoning, can be mixed with the soil to help liberate the metal from the clay and allow it to be taken up by the plant. Its use must be carefully monitored, so that the metals placed into solution are not leached into the groundwater before they can be drawn up by the root system.

At Ensign Bickford, the OB/OD area was divided into five zones based upon contamination. The Ensign Bickford remedial engineers first tilled nitrogen, phosphorus, and potassium fertilizers into the lead-contaminated soil. To raise the pH, dolomite lime ( $\text{MgCaCO}_3$ ) also was added. The areas were irrigated by an overhead spray system that additionally was used to provide supplemental foliar fertilizer that is absorbed through the leaf of the plant, not the roots.

During a single six-month growing season, an aggressive cultivation program was carried out. Indian mustard (*Brassica juncea*) was first planted then harvested, followed by sunflowers (*Helianthus annuus*), and then, after harvesting, there was

another planting of Indian mustard. Results were very encouraging. Total lead concentrations in soil decreased in four of the five test plots by about 25 percent, from 635 to 478 mg/kg, and no soil samples contained concentrations of lead above 4,000 mg/kg. Sunflower and Indian mustard plants successfully extracted lead at similar rates, about 1,000 mg/kg on a dry weight basis. Harvested plants were incinerated at an authorized disposal facility. Because of a high water table in Area 5, plant growth was not as optimal, and phytoextraction was less successful. Digging up and disposing of impacted soil off-site addressed contamination in this area.

As a result of this phytoextraction project, as well as other remedial efforts undertaken by Ensign Bickford, EPA and CTDEP have found that contaminated groundwater remains within the facility's property boundaries, is being effectively monitored, and does not pose an uncontrolled threat to nearby groundwater users.

**Environmental Protection Agency (EPA), U.S.** Between the mid-1700s and early 1800s the basic tenets of Western Europe in regard to labor-driven agriculture, animal- or wind-based transportation, and individual or small guild-organized production processes began to change. The Industrial Revolution, for example, introduced coal-powered machines that required large, centralized factories and were able to mass-produce high-quality, inexpensive products. Steam-driven locomotives and ships now could move enormous quantities of

goods and people rapidly and almost independently of weather. By the late 1800s, the internal combustion engine would be able to drive machines that quickly and efficiently plow fields, plant seeds, and harvest crops.

As these technological advances overtook Europe and North America, people began to view their relationship with the world in a different way. Survival was no longer a struggle based on dominating nature, and, as the waste and unusable by-products of these modern technologies began to accumulate in the air and water, a new sense of responsibility or stewardship toward the Earth and its resources began slowly to form among a small dispersed group of citizens. First articulated by Ralph Waldo Emerson, Henry David Thoreau, and other American writers and philosophers, transcendentalism (as it came to be known) was based in part on establishing a close, intimate connection with the natural world. Although never a significant political force in the United States, transcendentalism provided the basis for the conservation movement, whose aim was to preserve the country's natural resources for their continued, sustainable use by future generations. Championed by President Theodore Roosevelt, through the mid-1900s, conservationists were successful in establishing the National Forest Service, the National Park Service, Fish and Wildlife Service, Soil Conservation Service, and National Wildlife Refuge system as well as numerous other beneficial natural resource protection programs.

At the end of World War II, another industrial revolution was clearly emerging, this one based upon the rampant use of chemicals to tame nature. The nuclear age had started and the construction of some of the largest, most complex chemical processing facilities in the world was under way in Hanford, Washington; Oak Ridge, Tennessee; and Aiken County, South Carolina. In addition to the nuclear arms race, U.S. industries were expanding to include the development and manufacture of oil-based plastics, synthetic pharmaceuticals, and agricultural chemicals. The impacts on the environment and public health from the wastes of this chemical-based industrial revolution were more insidious, long-lasting, and difficult to see than smoky skies and oil-slicked water. They include cancer, genetic damage, and ecosystem destruction. The battle cry that the use of the new technologies and products could cause environmental problems arose from Rachel Carson's examination of indiscriminate pesticide use on public health and species diversity described in her 1962 book *Silent Spring*. This carefully documented analysis alerted people and policy makers that more attention to the potential adverse

consequences of agricultural chemicals and, by logical extension, other modern industrial processes was needed. The book, although roundly denounced by the chemical industry, became the most important document in the American environmental movement and indeed one of the most influential books of the 20th century.

### FORMATION OF THE ENVIRONMENTAL PROTECTION AGENCY

As public awareness of environmental issues grew, the government made several attempts to address the patchwork of local and statewide laws and regulations that dealt with pollution and waste management. Although ineffective and having little enforcement power, the Federal Water Pollution Control Act and Air Quality Act of the early 1960s were the first serious attempts to establish an organized, nationwide system of environmental and pollution control laws. These laws were a good start, but it was not until the disillusionment with government and other American institutions in the late 1960s and early 1970s, fueled by the war in Vietnam, coupled with several highly visible environmental disasters, that overwhelming public pressure would finally lead to a substantial federal response.

On January 1, 1970, President Richard M. Nixon signed into law a groundbreaking piece of legislation: the National Environmental Policy Act (NEPA). For the first time, the federal government would be required to examine the environmental consequences of an action, be it a permit for a dam in Colorado or the construction of a public housing project in Illinois. NEPA both legitimized and emboldened environmentalists, both in Congress and at the grassroots level. Environmental protection was now firmly on the national agenda, and more than 20 million Americans took to the streets on April 22, 1970, to demand stronger and better enforced laws to improve air and water quality. A 1970 report by the Nixon administration on government reorganization argued strongly that an independent agency was needed to coordinate all of the new environmental initiatives.

President Nixon, not a strong believer in government intervention in free market activities, signed the executive order that created the Environmental Protection Agency on December 2, 1970.

### FOCUS AND MISSION

Although not a cabinet level department, EPA has a mission and powers that are some of the most far-reaching in the federal government. Early on, the

founders of EPA decided that they needed to operate independently of the executive and legislative branches. The EPA's prime directive is to "protect human health and the environment," and the decisions it makes must be viewed as objective, unbiased, and not influenced by any governmental agency, program, or political agenda. This can only be accomplished if it operates as a stand-alone entity. As part of its protective mission, EPA establishes and enforces environmental protection standards, conducts environmental research, and provides assistance to others addressing environmental pollution. The EPA also assists the Council on Environmental Quality (formed as part of NEPA) in developing and recommending to the president new environmental protection policies.

The new agency was assembled from and assumed responsibility for all of the environmental programs that had been previously dispersed throughout the federal government. This included air pollution control, water hygiene and solid waste, and the control of selected radiological management issues from the Department of Health, Education and Welfare. The Food and Drug Administration reassigned its control over tolerance levels for pesticides, and the Department of the Interior transferred the functions of the Federal Water Quality Administration as well as portions of its pesticide research responsibilities.

The first EPA administrator, 38-year-old William D. Ruckelshaus, quickly set about establishing the culture of the new agency as one that viewed the environment holistically and would serve as an advocate for the public's interests in a clean environment. The EPA considered economic issues in its decisions but would not be driven by or beholden to them. One of the EPA's first enforcement actions was to challenge the cities of Detroit, Cleveland, and Atlanta to meet newly promulgated clean air standards or face federal prosecution. This aggressive stance toward environmental advocacy and compliance, although somewhat moderated over the years as the environmental attitudes of the public and regulated community changed, remains one of the main tenets of EPA's organizational culture.

## ORGANIZATION AND OPERATIONS

On a national level, the EPA is managed by an administrator. Appointed in 2009, Lisa P. Jackson is currently the 12th EPA administrator and is responsible for managing more than 17,400 employees and overseeing an annual budget of almost \$11 billion. Supporting the administrator in Washington, D.C., are three official offices and nine assistant administrators whose functions include the following:

### Office of the Chief Financial Officer

Manages the agency's payroll and makes payments to EPA grant recipients, contractors, and vendors. Also handles all accounting and financial reporting for the agency, in compliance with the requirements of the White House Office of Management and Budget and the Department of the Treasury. At present, the position is held by Barbara Bennett.

### Office of General Counsel

Acts as the legal adviser to EPA and provides legal support for agency rules and policies. It also supplies legal advice for case-by-case decisions such as permits and response actions and legislation. At present, the position is held by Scott Fulton.

### Office of Inspector General

An independent office within EPA that is made up of auditors, program analysts, and investigators who help ensure the integrity of agency decisions and operations. Although it is part of EPA, Congress provides the OIG funding separate from the agency, to ensure its independence. At present, the position is held by Arthur A. Elkins, Jr.

### Assistant Administrator for Administration and Resource Management

Responsible for management of human resource functions (hiring, firing, benefits, etc.) for headquarters employees, as well as agency-wide human resources (HR) policy development, strategic planning, and the direction of EPA's human resource programs. At present, the position is held by Craig Hooks (Acting).

### Assistant Administrator for Air and Radiation

Develops national programs, technical policies, and regulations for controlling air pollution and radiation exposure. OAR also addresses pollution prevention and energy efficiency, indoor and outdoor air quality, industrial air pollution, pollution from vehicles and engines, radon, acid rain, stratospheric ozone depletion, climate change, and radiation protection. At present, the position is held by Gina McCarthy.

### Assistant Administrator for Enforcement and Compliance Assurance

Pursues enforcement actions and provides compliance assistance to areas that yield the most environmental benefit or reduce risk to human health. Enforcement and compliance actions are organized around environmental problems and broad patterns of noncompliance rather than provisions of single statutes. At present, the position is held by Cynthia Giles.

### **Assistant Administrator for International Affairs and Tribal Affairs**

Helps safeguard the health and environmental safety of individuals in the United States and abroad by leading EPA's efforts to address global environmental issues. Works with experts from EPA's other programs and regional offices, government agencies, foreign governments, and international organizations to identify environmental issues of mutual concern and implement technical and policy options to address them. At present, the position is held by Michael DePass.

### **Assistant Administrator for Environmental Information**

Manages the information life cycle in support of EPA's mission. Identifies and implements innovative information technology and information management solutions that strengthen EPA's ability to achieve its goals. It ensures the quality of EPA's information, and the efficiency and reliability of EPA's technology, data collection, and exchange efforts, as well as online access services. At present, the position is held by Malcom D. Jackson.

### **Assistant Administrator for Chemical Safety and Pollution Prevention**

Promotes pollution prevention through innovative partnerships and collaboration. Evaluates pesticides to safeguard all Americans, including children, and ensure pesticides used near food are safe and protective of the environment and ecosystems. At present, the position is held by Steven Owens.

### **Assistant Administrator for Research and Development**

The scientific research arm of EPA. Provides the science and technology information for the agency. Conducts research on ways to prevent pollution, protect human health, and reduce risk. At present, the position is held by Paul Anastas.

### **Assistant Administrator for Solid Waste and Emergency Response**

Offers policy, guidance, and direction for the agency's solid waste and emergency response programs. It develops guidelines for the land disposal of hazardous waste and management of underground storage tanks. Provides technical assistance to all levels of government to establish safe practices in waste management and administers the brownfields program, supporting state and local governments in redeveloping and reusing potentially contaminated sites. Responsible for the management of the Superfund program to respond to abandoned and active

hazardous waste sites and accidental oil and chemical releases as well as encourage innovative technologies to address contaminated soil and groundwater. At present, the position is held by Mathy Stanislaus.

### **Assistant Administrator for Water**

Works to ensure drinking water is safe as well as to restore and maintain oceans, watersheds, and their aquatic ecosystems. Protects human health, supports economic and recreational activities, and provides healthy habitat for fish, plants, and wildlife. At present this position is held by Peter Silva.

On a local level, EPA has divided the United States into 10 regions, each one assigned to a regional administrator, technical staff, and environmental protection goals, depending upon the needs of the geographic area it serves. At present, these position are held by the individuals listed in the table on page 221.

## **EPA REGIONAL OFFICES**

In addition to supporting and enforcing environmental initiatives developed in Washington, many of the EPA regions have their own subspecialties. For example, EPA Region 5 provides expertise related to air pollution and air pollution control, because of the presence of the many heavy industries and coal-burning power plants in this part of the country. Region 10 has extensive experience in the clean up of radiologically contaminated sites in response to the Hanford site along with other large, government-owned nuclear processing facilities throughout the area.

## **ACCOMPLISHMENTS AND FUTURE GOALS**

The record of accomplishment for the almost 40-year-old agency is impressive and includes the following major accomplishments:

- **1970s:** Establishes national air quality standards for the six most common types of pollutants: sulfur oxides, particulate matter, carbon monoxide, photochemical oxidants, nitrogen oxides, and hydrocarbons. Bans the use of dichlorodiphenyltrichloroethane (DDT) and works with Congress to pass substantial amendments to the Federal Water Pollution Control Act and Ocean Dumping Act. Starts phaseout of leaded gasoline and issues first permits regulating the discharge of municipal and industrial wastewater. Works with Congress to pass Safe Drinking Water Act. Bans the use of the

## EPA REGIONAL OFFICES

Region Number	2010 Administrator	Area Served
1 (EPA New England)	Curt Spalding	Connecticut, Maine, Massachusetts, New Hampshire, Rhode Island, and Vermont
2	Judith A. Enck	New Jersey, New York, Puerto Rico, the U.S. Virgin Islands, and seven Native American tribes
3 (EPA Mid-Atlantic)	William T. Wisniewski (acting)	Delaware, Maryland, Pennsylvania, Virginia, West Virginia, and District of Columbia
4 (EPA Southeast)	Stanley Meiburg (acting)	Alabama, Florida, Georgia, Kentucky, Mississippi, North Carolina, South Carolina, Tennessee, and six Native American tribes
5	Bharat Mathur (acting)	Illinois, Indiana, Michigan, Minnesota, Ohio, Wisconsin, and 35 Native American tribes
6	Al Armendariz	Arkansas, Louisiana, New Mexico, Oklahoma, Texas, and 65 Native American tribes
7	Karl Brooks	Iowa, Kansas, Missouri, Nebraska, and nine Native American tribes
8	James B. Martin	Colorado, Montana, North Dakota, South Dakota, Utah, Wyoming, and 27 Native American tribes
9 (EPA Pacific Southwest)	Jarred Blumenfield	Arizona, California, Nevada, Hawaii, and 147 Native American tribes
10 (EPA Pacific Northwest)	Michelle Pirzadeh (acting)	Alaska, Idaho, Oregon, Washington, and Pacific Northwest Indian Country

pesticides heptachlor and chlordane. Works with Congress to pass the Toxic Substances Control Act and the Resource Conservation and Recovery Act (RCRA). Works with Congress to pass the Clean Water Act and substantial amendments to the Clean Air Act. EPA bans aerosol fluorocarbons and the manufacture of polychlorinated biphenyls (PCBs).

- **1980s:** Supervises the cleanup at Three Mile Island. Works with Congress to pass the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA). Identifies the first 114 Superfund sites. Works with Congress to pass the Asbestos School Hazard Abatement Act. Bans the use of the pesticide 1,2-dibromoethane (EDB). Works with Congress to pass Hazardous and Solid Waste Amendments Act, Superfund Amendments and Reauthorization Act, Asbestos Hazard Emergency Response Act,

and substantial amendments to the Safe Drinking Water Act. EPA sets standards for underground storage tanks, provides technical support urging the ratification of the Montreal Protocol (phasing out chlorofluorocarbons [CFCs]). Works with Congress to pass the Federal Insecticide, Fungicide and Rodenticide Act Amendments of 1988, the Indoor Radon Abatement Act, and the Ocean Dumping Ban Act.

- **1990s:** Works with Congress to pass the Pollution Prevention Act and the Clean Air Act Amendments. EPA issues final drinking water standards for 23 chemicals. EPA and New York mark end of offshore dumping of sewage sludge. Designates passive smoke a human carcinogen. Safe Drinking Water Act Amendments of 1996 passed. Finalizes leaded gas ban. Implements lead-based paint Right-to-Know. United States and Canada move to eliminate toxics in Great Lakes.

- **2000s:** Bans most uses of the pesticide Dursban. The United States signs Convention on Persistent Organic Pollutants. Awards brownfields grants to assess the contamination of abandoned industrial and commercial properties. Issues Strategic Plan for Homeland Security. Announces the Clean School Bus USA program. Issues the Clean Air Nonroad Diesel Rule. Establishes more protective eight-hour ozone and fine-particulate standards. Issues the Clean Air Interstate Rule and the Clean Air Mercury Rule. Becomes the first major federal agency to purchase green power equal to 100 percent of its annual electricity use. Strengthens standards for particulate matter with a diameter of 2.5 microns or less (PM<sub>2.5</sub>) particle pollution. Superfund marks 1,000th construction completion.

As the EPA looks toward the future, it faces some daunting challenges. The environmental implications of global climate change are going to dominate more of our economic and environmental policy decisions, and the EPA will be a central figure in the development of the policy approach to this vital issue. Coupled with climate change will be the need to develop programs that minimize impacts from expanded and more aggressive searches for dwindling natural resources while ensuring the sustainability of those resources for future generations. Ecosystem loss and habitat destruction related to population and development pressures will increase, and additional scientific research needs to be done on the effects of estrogen and other hormones (which are resistant to conventional treatment technologies) that are being found with alarming regularity in public water supplies.

Although EPA is decried by its detractors as slow, inefficient, and either too soft or too hard on the industries and practices it regulates, there is little doubt that the air is cleaner, the water purer, and wastes are managed in a more environmentally responsible manner. Although much remains to be done, the EPA has the infrastructure that will allow it to adapt to the demands of the American people for a clean environment and the needs of the U.S. economy to remain viable in an internationally competitive world.

## environmental regulations overview

Environmental laws and regulations have been in effect in some countries for hundreds of years. Some of the earliest examples include passages in the Bible (Book of Genesis), Torah, and Quran commanding us to treat the Earth and its resources with respect. A more specific example occurred in 1402, when the English Parliament, in an early attempt to improve local air quality, passed a law banning the burning of coal in London.

Conservation laws that regulated the use and preservation of natural resources appeared regularly throughout American colonial times. In 1629, land use guidelines were promulgated in New England regulating plantation (farm) design and prohibiting activities that interfered with common resources such as water or damaged the property of others. Virginia passed laws regulating fishing, and Massachusetts, in the 1790s, developed some of the earliest statutes to promote wetland and coastal preservation. As industrialization continued, the western states evolved a complicated set of environmental regulations related to the use of water and mining. The modern body or set of environmental laws, however, did not begin to appear until the 1960s. They were based on three major legal precepts, common law, case law, and statutory law.

## BASES FOR ENVIRONMENTAL LAWS

United States common law is the general body of rules and precepts that originated in England and is not the result of legislative action, but rather derives its authority from unwritten principles related to

**Cartoon diagram illustrating many sources of pollution and media affected and the major federal regulations enacted to address them**

usages and customs that have been upheld by the courts over a long period. It is founded on a cultural view of fair, reasonable, and just actions. Common law can change over time and is intended to evolve with society. Under common law, a tort (civil wrong) from which relief is sought through the court can be based on every individual's or company's obligation not to cause harm to someone else as a result of its actions or inaction. A contract or written agreement with a company or person is not needed to bring a tort, only a claim that injury has occurred because of failure to avoid harm. The three most common torts related to environmental issues are nuisance, trespass, and negligence.

### Nuisance

A nuisance is an activity that interferes with the use of property through irritation, obstruction, or danger. Nuisances can range from obnoxious odors emanating from a nearby chemical plant (public nuisance, affecting many people) to a barking dog that will not be quieted (private nuisance, affecting an individual). In adjudicating nuisance torts, the courts weigh many factors, such as whether they are materially affecting physical or mental health, whether there are societal benefits (e.g., jobs) associ-

ated with the nuisance, and whether the nuisance predated occupancy of the property.

### Trespass

Trespass is an interference with the possession of property. This can include destruction or taking of personal property as well as unlawful or forcible entry. In environmental matters, trespass is most often claimed when air or water pollution physically migrates onto or under another's property and prevents the owner from using land, home, or business for its intended purpose.

### Negligence

Negligence is the unintended damage caused by a person's or company's failure to protect others from its actions. In evaluating negligence claims, the courts use the "reasonable man" test. What precautions would a prudent and sensible person have taken to avoid harm in this situation? The plaintiff must demonstrate that the defendant breached a duty or standard of care. One case illustrating a breach of the standard of care was a suit brought by Nissan Motor Corp against a Maryland shipyard. The shipyard chose to begin a large repainting operation on a windy day. As a result, windborne residues

## Epidemiology and Health Effects

A major tool used by toxicologists in the measurement of the disease-causing potential of a substance is an epidemiological study. Epidemiology is focused on the response of groups, populations, or communities to disease or injury. Epidemiologists study the factors that influence the distribution of illness or injuries in a population. They base their work on three fundamental precepts: (1) that the disease or injury does not occur at random and that there is a reason why certain groups or communities become ill or are hurt; (2) that the disease or injury has causal and preventive factors; and (3) that the disease or injury is not randomly distributed throughout a population.

Epidemiological studies attempt to identify the distribution and determinant factors of diseases and injuries in human populations. They are designed to study the differences in disease distribution in populations or population subgroups systematically and are used to test hypotheses concerning causal and pre-

ventive factors. There are four common types: cohort studies, case control studies, occupational epidemiological studies, and cross-sectional studies. Each is described in the following table.

### EXAMPLE OF CHOLERA

A good example of the value of epidemiology is the disease cholera. Cholera is a bacterial infection whose first symptoms include severe diarrhea, often accompanied by vomiting. The body rapidly loses fluid and salts, causing muscle cramps, unquenchable thirst, and cold, wrinkled skin. If lost fluids are not replaced, coma and death usually follow within 12–24 hours. Intravenous infusion of saline solution or ingestion of electrolyte solution is the preferred course of treatment. In the first half of the 1800s, four major cholera epidemics swept through England and Wales, killing almost 100,000 people. There was no cure, there was no treatment, and physicians were widely

**TYPES OF EPIDEMIOLOGICAL STUDIES**

Study Type	Description	Advantages	Disadvantages
Cohort	Follows a group of healthy people with different levels of exposure and assesses what happens to them over time	Exposure is evaluated and studied before the health outcome is known. This allows for a clear study and identification of causative factors.	Expensive, time-consuming, and logistically difficult to implement.
Case control	Investigates exposed individuals, or "cases," and nonexposed individuals, or "controls," and compares the health of both groups over time	Enables evaluation of rare outcomes without having to follow thousands of people. Quicker, cheaper, and easier to conduct than cohort studies.	Potential for bias is greater because only one type of health effect has been selected for evaluation.
Occupational	Selects and evaluates people working at particular jobs or with particular exposures	Workers often have substantially higher exposures to certain risk factors than the typical population. This increases the chance of detecting a health effect.	The working population is substantially different from the nonworking one. Makes it difficult to generalize to the overall population.
Cross sectional	Compares similar groups in terms of their current health exposure status and assesses their similarities often used to select populations for case control or cohort studies	Easy and quick to perform; provides a snapshot of a particular group.	A cause cannot be inferred, as only current health and exposure issues are evaluated.

divided on the cause and spread of the disease. Some blamed “bad air” from swamps, weak blood, poor nutrition, or even a “sinful state.”

In 1855, an English doctor decided to take a new approach to this mysterious disease. Dr. John Snow left his comfortable Harley Street office and went to a London neighborhood where cholera had been just been reported. His objective was to determine why the people in a particular group of apartment buildings had become sick, but not those across the street, or down the block. His 1855 paper “On the Mode of Communication of Cholera” is widely recognized as one of the first epidemiological investigations, and it established him as the founder of modern epidemiology.

Dr. Snow examined the medical histories of those who had the disease, their diets, their pets, their workplaces, their areas of travel, and their sleeping habits. He examined their apartments and, after a careful inspection of each building, found what he thought might be the cause. Dr. Snow noted that they all received their water from a single nearby well, and that this well was located very close to a cesspool used for the disposal of human wastes. He saw that the cesspool drain would leak or overflow, and human waste would sometimes enter the area near the well and probably mix with the drinking water. He checked other apartment buildings in the neighborhood where no cholera had been reported and found that those people had drawn their drinking water from a different well.

With this information, and drawing upon the concepts of disease causation being proposed in the relatively new field of bacteriology, Dr. Snow concluded that there was something in the cesspool-contaminated drinking water that was causing people to become sick. He proposed that drinking water supply systems should be isolated from those carrying human waste. In other words, keep feces out of the drinking water and the incidence of cholera should decrease. Although they seem obvious, Dr. Snow’s findings were controversial for the time and widely debated within the scientific and medical community. Eventually, as Snow successfully pressured local neighborhoods to implement some of his recommendations, the incidence of cholera began to decline.

Perhaps the most famous modern epidemiological study is the 1964 U.S. surgeon general’s report that conclusively linked smoking with lung cancer. Another is the Framingham Heart Study, which began in 1949. This study, which continues to track and evaluate to this day thousands of people living in Framingham, Massachusetts, provided some of the

first conclusive evidence that related heart disease to such lifestyle characteristics as a high-fat diet and lack of exercise.

### LABORATORY TESTING OF HEALTH EFFECTS

There are numerous ways a chemical or pollutant can impact a person or animal’s health. Administering different doses of a substance to test animals over their lifetimes and observing the related health effect or response is typically how noncarcinogenic toxicity is assessed. Using this method, toxicologists try to identify the lowest dose that causes an observable effect or response. These responses include damage to internal organs such as the kidneys or liver, behavioral modifications indicating changes in brain chemistry or function, or modifications in the animal’s blood chemistry suggesting interference with normal cellular activities. Once identified, this dose is designated as the lowest observable effect level, or LOEL. The LOEL is reported in milligrams of substance per kilogram of body weight, or in parts per million of substance in food.

#### Lowest Observable Effect Level (LOEL)

Hydramethylnon is a very effective delayed-action pesticide that is ideal for use in bait products. After a single feeding to target insects (usually roaches and ants), there are no immediate indications of poisoning. However, within a few hours, the insects become lethargic and stop eating. This condition progresses until the insects die, usually within 24–72 hours. Hydramethylnon interferes with the insect’s energy-producing mechanisms on a cellular level.

After the hydramethylnon bait is ingested, the roaches and ants serve as carriers of the active ingredient to harborage and colonies. Cockroaches are coprophagous; they eat their own feces and the feces of other roaches. They also feed on each other. After consuming a lethal dose of bait, cockroaches return to the harborage, where they excrete feces containing hydramethylnon. As other cockroaches consume the contaminated feces, they also receive a lethal dose. When the roaches die, other roaches may consume their contaminated carcasses. Field trials have shown that one cockroach that ingests a lethal dose of hydramethylnon can cause the death of more than 40 other cockroaches.

Ants carry the hydramethylnon-saturated bait to the colony, where the larvae digest and regurgitate it as a liquid to feed the queen and the rest of the colony.

*(continues)*

(continued)

The delayed action of hydramethylnon allows foraging worker ants to return to the colony with the bait before they succumb to the poison.

To determine a (human) LOEL for hydramethylnon, the U.S. Environmental Protection Agency (EPA) used the results of a study on two generations of rats in which varying doses of this substance (0, 25, 50, and 75 mg/kg) were fed to 30 male and 30 female rats and their offspring. In this study, testicular degeneration was noted in five of 30 rats at 75 mg/kg and in one of 30 rats at 50 mg/kg. In 1998, on the basis of this incidence of testicular toxicity as well as the related dose-response curve, EPA set a LOEL of 50 mg/kg in food for hydramethylnon. Other toxicological experiments tended to support this LOEL, although data from a three-generation rat study caused the California Office of Environmental Health Hazard Assessment to establish a much lower LOEL of 0.12 mg/kg.

#### No Observable Effects Level (NOEL)

The next step in the assessment of noncarcinogenic effects was to identify the no observable effects level, or NOEL. This is the highest dose possible before there are any noticeable health effects. The animal species being studied can be exposed to a substance's NOEL and no adverse health effects will occur. The NOEL measured for hydramethylnon, based on dog, rat, and rabbit studies, is around 3–5 mg/kg. People, however, are genetically and physiologically more complicated than most laboratory animals and may be more or less sensitive to the chemical or substance being evaluated, so the NOEL is not considered a "safe level."

The NOEL practice is not without risk. Thalidomide, a drug developed in the 1950s and promoted as a sleeping pill for pregnant women, caused no adverse effects in test animals but resulted in severe birth defects in humans. Today, the standard practice for toxicologists is to divide the NOEL by a safety factor, usually 100, in order to calculate a dose or exposure standard that will be protective of the public health. For example, if the NOEL for a substance tested on laboratory rats were found to be 100 mg/kg, the "safe level" for humans would be 1 mg/kg. This safe level is also known as the reference dose (RfD). It is a numerical estimate of a daily oral exposure to the human population, including sensitive subgroups, such as children, that is not likely to cause harmful effects during a lifetime. RfDs generally are used for health effects that are thought to have a threshold, or low dose limit, for producing an adverse reaction. Some examples of RfDs for common contaminants are

provided in the table. The EPA determined the RfD for hydramethylnon at 0.0003 mg/kg/day. They also have classified it as a possible human carcinogen, and hydramethylnon's use in Europe was banned in 2003.

#### HAZARD QUOTIENT (HQ)

The RfD also is used in determining the hazard quotient (HQ) for a given substance. The HQ is the ratio of a single substance exposure level, over a specified period, to a RfD for that substance derived from a similar period. This ratio provides an indication as to the degree of hazard present as a result of exposure to that substance. As an example, Dalapon is a herbicide and plant growth regulator that controls annual and perennial grasses as well as cattails and rushes. Dalapon is selective, meaning that it kills only certain plants while sparing nontarget vegetation. This makes it very useful in improving the productivity and management of such large food crops as sugarcane and sugar beets. Dalapon also is used on fruits, potatoes, carrots, asparagus, alfalfa, and flax.

Dalapon is thought to be only moderately toxic to humans. Unless proper precautions are observed, skin and inhalation exposures may affect Dalapon production workers, pesticide applicators, and those working in agriculture. Acute exposure causes loss of appetite, slowed heartbeat, skin and eye irritation, and gastrointestinal disturbances such as vomiting and diarrhea. Dalapon also is an acid that may damage sensitive body tissues and especially the eyes. The EPA calculated an RfD for Dalapon of 0.03 mg/kg (of body weight) per day. No adverse health effects should occur to the most sensitive receptor from exposure to this concentration of Dalapon over a lifetime. If a person lives beside a farm where Dalapon is used, however, and the local health department finds that it has been detected in the well water at a concentration that results in an exposure of 0.02 mg/kg per day, a question is raised about potential health effects from exposure to this compound at this concentration. To determine whether there is cause for concern, the person should calculate the HQ.

Dalapon RfD = 0.03 mg/kg per day

Dalapon exposure = 0.02 mg/kg per day

HQ = exposure divided by RfD

HQ = (0.02 mg/kg per day) / (0.03 mg/kg per day)

HQ = 0.7

RfDs OF TYPICAL POLLUTANTS		
Type	Contaminant	Referenced Dose or Oral Slope Factor (mg/kg /day)
Metals	Arsenic	1.5
	Beryllium	4.3
Volatile organic compounds	Benzene	0.055
	Carbon Tetrachloride	0.13
	Chloroform	0.0061
	Tetrachloroethene	0.052
	Trichloroethene	0.4
Semivolatile organic compounds	Benzo(a) pyrene	7.3
	Benzo(b) Fluoranthene	0.73
	Pentachlorophenol	0.12
	Chrysene	0.0073
Pesticides/herbicides	Chlordane	0.35
	DDT	0.2
	Heptachlor	1.6
Others	PCBs	2

As long as the HQ is less than 1, it is below the threshold where a noncancerous effect is expected. In this case, the Dalapon-contaminated groundwater is safe for the time being, but it should be tested periodically to make sure the concentration does not increase.

### HAZARD INDEX (HI)

The real importance of HQs comes into play when there is more than one substance present to which a receptor may be exposed. If, for example, Aldicarb, a common herbicide, is added to the Dalapon-contaminated groundwater, a different HQ results. Aldicarb is a very aggressive insecticide used to control mites, nematodes, and aphids. It is applied directly to the soil for the protection of cotton, peanut, and soybean crops. Aldicarb has an RfD of 0.0013. If the concentrations in well water result in an Aldicarb exposure of 0.002 mg/kg per day, will people's health be affected? Calculating the HQ for Aldicarb, it is found that the HQ is less than unity (1), indicating that at this concentration, the risk is acceptable.

Aldicarb RfD = 0.002 mg/kg per day

Aldicarb exposure = 0.001 mg/kg per day

HQ = exposure divided by RfD

HQ = (0.001 mg/kg per day) / (0.002 mg/kg per day)

HQ = 0.5

The Dalapon that is also present in the water complicates the situation. Individual HQs do not consider the synergistic effects of exposure to more than one substance. For that, the hazard index, or HI, must be calculated. The HI takes into account exposure to more than one substance and is the sum of all the individual HQs. The HI is used to evaluate the risk resulting from exposure to more than one pollutant or from multiple exposure pathways (inhalation and ingestion).

The HQ for Dalapon is 0.7, and the HQ for Aldicarb is 0.5, both below unity (1) and, therefore, individually

(continues)

(continued)

not a cause for concern. However, calculating the HI as follows:

$$HI = HQ1 + HQ2 + HQ3 + \dots$$

$$HI = HQ_{\text{Dalapon}} + HQ_{\text{Aldicarb}}$$

$$HI = 0.7 + 0.5$$

$$HI = 1.2$$

The HI is 1.2, greater than unity. Although separate HIs are usually calculated for chronic, subchronic, and shorter-duration exposures to specific target organs such as the kidneys or liver, the results from this example indicate that there is a significant risk of a potential adverse health effect from exposure to these substances at the reported concentrations. Corrective actions would be needed.

from paint spraying operations were deposited on cars stored at an adjacent parking lot. The court decided the shipyard was negligent and awarded Nissan appropriate monetary damages.

### Strict Liability

Another concept essential to understanding and applying common law to environmental claims is that of strict liability. A person or company can be held liable for damages for those activities that are considered hazardous, even if no negligence is proven. For example, walking a lion down a crowded sidewalk is dangerous, even if the lion has been trained, is well-fed, is wearing a muzzle, is declawed, and is on a leash, and there is a permit for the possession of the lion. Despite all these precautions, if the lion pounces on someone and injures him or her, the owner is held strictly liable. Similarly, the manufacturer of an extremely toxic chemical will be held strictly liable if a release occurs and injures residents living near the plant, even if the company has modern, state-of-the-art pollution control devices. Most of the environmental laws and regulations administered by the U.S. Environmental Protection Agency (EPA) (in particular the Comprehensive Environmental Response Compensation Liability Act or CERCLA), as well as many state agencies, are based on this concept of strict liability.

Case law is based on judicial decision and precedent, rather than on statutes passed by legislative bodies. Judges evaluate each claim or tort and

take prior decisions on similar matters into account before rendering a decision weighing those and other considerations. In contrast, statutory law is a set of written requirements established by a legislative or authoritative rule-making body to address a public need or clarify the functions of a governmental agency. Both case law and statutory law have played a role in the development and enforcement of environmental policies and regulations.

Modern environmental law includes a wide variety of statutory law, case law, and common law interpretations and precedents as well as federal, state, and local governmental regulations, policies, guidelines, and requirements. These laws and regulations attempt to control and manage the interaction of human activities with the natural environment including air, water, and soil, as well as the interaction of these media with the living ecosystem. Many environmental regulations and programs are interrelated and overlap, making them difficult to resolve. Ultimately, the system of environmental laws in the United States is designed to force those who conduct actions that could damage the environment to minimize potential environmental risks and to be liable if they harm public health or damage the use of soil, air, water, or the ecosystem. There are 12 major federal laws that govern human interactions with the environment, and EPA has delegated some or all of the enforcement responsibilities to the states that have equivalent environmental programs.

## NATIONAL ENVIRONMENTAL POLICY ACT (NEPA)

Passed by Congress in 1969 and signed into law by President Richard Nixon in 1970, NEPA (42 U.S.C. §§ 4321–4370c) is the first major statute in the United States that involved assessment and evaluation of the environmental consequences of human activity. NEPA was groundbreaking legislation and legitimized the environmental consciousness that had begun to sweep the nation. Its main purpose is to ensure that potential environmental impacts are given equal weight in federal decision-making processes to more traditional considerations such as economic and tax consequences, public and societal benefits, and military or diplomatic advantages.

### Requirements

NEPA requires that before any proposed federal action that has the potential to affect the quality of the human environment significantly can take place, a systematic and careful review of the environmental implications of that action must be undertaken. This is done through the preparation of an Environmental Impact Statement, or EIS. Using guidelines established by the President's Council on Environmental Quality (CEQ), the EIS must contain a description of the environmental impacts (both good and bad) of the proposed action, a list of adverse impacts of the proposed action, a description of reasonable alternatives to the proposed action, and an accounting of natural resources that are irreversibly and irretrievably committed by the proposed action. The NEPA requires that the EIS for a proposed action be made available for public review and comment. EISs can be large, complicated, and highly technical documents that take years to prepare.

Certain minor federal actions do not require the preparation of an EIS. These are referred to as categorical exclusions, or CatEx, decisions and include such actions as improvements to existing rest areas and truck weigh stations along interstate highways, bus and railcar rehabilitation, and alterations to facilities or vehicles in order to make them accessible for the elderly or handicapped. Other, more substantial but not environmentally insignificant actions can be evaluated under NEPA through a more streamlined process called an Environmental Assessment, or EA. The EA is a shortened, more concise version of the EIS, usually only 15–20 pages long. It contains many of the same elements as an EIS, but EAs are not required to have the weighty and exhaustive analyses that typically are contained in EISs. When a federal agency is not sure whether an EA or EIS is required, it can petition the CEQ for guidance and a finding of no

significant impact, or FONSI, can be issued, obviating the need for any type of environmental analysis. FONSIs are rarely granted when major federal actions are being contemplated.

The preparation of EISs for most major programmatic or construction activities has become widespread because so many private and state development activities rely on federal permits or funding. Usually, the federal or state agency sponsoring the project charges the prime contractor or engineering firm with the responsibility to prepare the EIS. A public scoping process is used to identify the environmental issues requiring in-depth analysis. Then the scientific evaluations of water, soil, air quality, ecology, and so on, are performed, and the data are compiled, analyzed, and presented in a draft EIS, or DEIS. This draft then is forwarded to the lead agency, the governmental body with the primary responsibility for the project. After review, the DEIS is published and made available for public comment. A final EIS, or FEIS, which must address each of the comments received during the public review period, is issued.

### Objectives

NEPA and the EIS process are not intended to prevent damage to the environment, and federal agencies can still approve projects that have significant adverse environmental impacts. NEPA simply requires that these adverse impacts be identified and evaluated and that the agency consider the alternatives. If the agency deems that the benefits outweigh the negative environmental consequences of a project, they may still approve it. NEPA allows the public concerns to be heard, assessed, and included in that evaluation. It also ensures a high degree of transparency in the decision-making process and provides an opportunity for those most affected to apply political and scientific pressure to ensure adverse effects are mitigated as much as possible, even if project costs increase.

NEPA remains one of the cornerstones of American environmental law and policy, and its effective and efficient implementation continues to be a key goal of the CEQ and most federal agencies. Although many governmental bodies chafed early on at what they saw as interference with their regulatory authority, NEPA has now become fully integrated into the policy and strategic planning components of both federal and state governments.

## CLEAN AIR ACT

First passed in 1967 as a set of guidelines to help states improve their air quality, the Clean Air Act (CAA) has evolved into one of the most dominant

pieces of federal environmental legislation currently in effect. As air quality continued to deteriorate in the United States through the 1970s, it became clear that the technical and political issues associated with air pollution were too encompassing for the states to address by themselves. As a result, in 1977 and in 1990, the CAA was amended and became a very stringent command-and-control regulatory program.

### Requirements

The Clean Air Act of 1977, and its amendments in 1990, established the National Ambient Air Quality Standards (NAAQS), which limit the amounts of pollutants an industrial or commercial facility can discharge into the atmosphere. The limits are intended to be protective of public health, for both short-term (eight hours) and long-term exposures. The NAAQS standards have been the subject of numerous legal actions, both pro and con.

Under the CAA, each state has to demonstrate how it intends to achieve compliance with NAAQS. This is done through a State Implementation Plan, or SIP. The SIP must list the allowed emissions and their levels. It must describe the monitoring program for compliance with the emission limits and procedures to review and approve new major sources of air emissions (more than 100 tons [90 metric tons] of pollutants per year) and minor sources (less than 100 tons [90 metric tons] per year) that are proposed for construction. The SIP must account for pollution that may drift into the state from areas outside its boundaries and have an enforcement program designed to track down and punish polluters. The SIP is intended to be a “living” document, one that is revised and updated on a regular basis to take into account changing economic conditions and technological advances. For those states that fail to implement and update their SIPs, the federal government can withhold highway funds and implement other punitive measures.

Those portions of a state that are unable to achieve compliance with NAAQS regularly are called nonattainment areas and are subject to special controls under a SIP. If an industry wishes to expand or build a new facility and increase the level of air pollutants it will emit in a nonattainment area, it must obtain reductions in these same pollutant levels from other businesses, often at ratios of greater than one for one. For example, if a utility wants to build a new power plant that will emit 50 tons (45 metric tons) of particulate matter with a diameter of 10 microns or less (PM<sub>10</sub>) per year within a nonattainment area, it must find other facilities within the same area that are willing to reduce their particulate discharges by a similar

amount, or even more. The utility can offer to buy PM<sub>10</sub> emission credits—levels of particulate that other businesses are permitted to emit, but are not emitting because of shut-down production lines, less business, or the like. The utility can apply these credits toward the operation of its new power plant.

Emission credit trading is a lucrative business in certain parts of the United States. One ton (0.9 metric ton) of sulfur dioxide emissions has a market value in some areas of about \$10,000 per year. Many environmentalists view this as a loophole in the regulations that allows businesses to continue to emit high levels of pollutants. Many companies praise it as an innovative way to keep the economy growing and let the marketplace decide the value of projects.

Existing sources of air pollution in attainment areas must comply with the much stricter requirements in the SIP related to the New Source Review (NSR) portion of the Clean Air Act for the Prevention of Significant Deterioration, or PSD. One of the major requirements of the New Source Review PSD is that the facility must install and utilize the Best Available Control Technology (BACT) to manage its emissions. BACT achieves the maximal degree of emission reduction possible, taking into account cost, energy, and environmental factors. These technologies typically are very costly to install and operate.

For new sources of proposed air pollution in nonattainment areas SIP standards are even stricter. They must use technologies that achieve the Lowest Achievable Emission Rate (LAER). The LAER test includes not only emission technologies for the proposed new emission source, but for any other similar technology in a related business. For example, if a coal-fired power plant claims that a certain type of wet scrubber fulfills its LAER obligation, the regulatory agency can survey the mining industry, the chemical industry, and other businesses where similar emissions are produced, and, if a better device is identified, they can require that the power plant install it even if it is not typically used to control power plant emissions.

One area of the CAA that has been controversial is the modification rule under New Source Performance Standards (NSPS). As required by CAA, EPA must promulgate emission standards for certain industries that must be met when they upgrade or expand their businesses. NSPS are much tougher than the emission standards that many facilities were originally permitted to operate under before CAA was passed. The controversy is related to trying to define a modification. Many environmental groups claim that any type of major maintenance (e.g., rebuilding or replacing a worn turbine), change

in a production line, or increase in production volume is a major modification and should require the facility to meet the more stringent NSPS. This situation requires the installation of expensive Maximum Achievable Control Technology (MACT). These are air pollution control devices that result in the maximal degree of pollution reduction that is achievable given economic, energy, and environmental considerations in the source category (power plants, chemical factories, etc.). Business groups assert that they need some flexibility in the application of NSPS in order to operate their plants efficiently and respond quickly to changes in market conditions. EPA generally applies the NSPS upgrade requirements when a facility has an increase in emissions related to a physical or operational change in plant activity. Both industry and environmental groups have not been satisfied with this approach, and the enforcement of NSPS is currently being adjudicated.

CAA imposes limits on the emission of sulfur oxides, one of the major causes of acid rain, as well as establishing class I air quality areas (primarily near national parks) where additional restrictions are placed on businesses that emit air pollutants. Upper atmospheric ozone layer protections also are included in the CAA, which requires the phaseout of chlorofluorocarbons and other ozone-depleting substances. Finally, the CAA established, under a section called Title V, one of the most rigorous operational permitting programs in the world. Under Title V, each plant or business that emits 100 tons (90.7 metric tons) of air pollutants or more per year must inventory its sources, estimate the amount of pollution from each source, and propose a plan to eliminate that emission or bring it into compliance with applicable CAA requirements (PSD, NSPS, etc.).

Extensive monitoring requirements are written into the Title V permit, and penalties for noncompliance can range up to \$25,000 per day. In 2009, the EPA carried out 10,000 inspections of Title V facilities and imposed fines of almost \$2 billion for various operational and monitoring infractions. They also referred several hundred cases to the Justice Department for possible criminal prosecution. The CAA is complex and far-reaching legislation that has given the federal and state governments the tools to identify and regulate industrial and commercial (stationary) sources of air pollution. It is one of the main reasons why the skies over America are clearer and the air easier to breathe than only a few years ago.

### CLEAN WATER ACT

The short-term environmental objective of the Clean Water Act (CWA), passed in 1972 as an amendment

to the Federal Water Pollution Control Act, is to make every water body in the United States “fishable and swimmable.” Longer term, it seeks to restore and maintain the chemical, physical, and biological integrity of the nation’s water. These lofty goals are to be attained through a variety of mechanisms inherent in the act. These include:

- preventing discharges to surface and groundwaters, except those that have been authorized in compliance with provisions of the CWA
- establishing a system for preventing, reporting, and cleaning up spills
- setting limits on the amounts and types of pollutants that can be discharged and making sure that those discharges are controlled and monitored through a facility-specific permit program
- vigorously and uniformly enforcing permit conditions and those that violate the provisions of the CWA

### Requirements

The CWA broadly defines a pollutant as anything that is added to the navigable waters of the United States including solids, liquids, and thermal pollutants. To qualify for inclusion under the CWA, the pollutant does not necessarily have to be toxic or dangerous, but it must be connected to interstate commerce. The CWA also differentiates between a point source and a nonpoint source of pollution. Point source pollution is anything that comes out of a pipe, ditch, channel, or other human-made conveyance. Nonpoint source pollution includes discharges from less well-defined mechanisms, such as runoff from farm fields or roads.

Regardless of its source, the CWA requires that discharge of a pollutant must be under the terms of a National Pollutant Discharge Elimination System (NPDES) permit. These permits typically are issued for five-year intervals and require a description of the discharged pollutants, their concentrations, and monitoring plans. The NPDES permitting process is long and complicated and includes ample opportunity for public input and comment. Once issued, NPDES permits give the regulatory agency wide authority to enter an industrial establishment and inspect the discharge.

Under the CWA, effluent discharge guidelines have been established for most types of industrial operations. These guidelines set limits on the types of discharges. For pollutants typically associated

with domestic sewage treatment (BOD, TSS, fecal coliform, pH, and oil and grease), the permittee is required to install Best Conventional Technology, or BCT. These are technologies that are effective and able to remove contaminants for a reasonable cost. This is the simplest level of treatment allowed under the CWA and is consistent with the relatively low level of risk posed by this type of pollutant.

For other types of industrial pollutants, the CWA requires that dischargers use Best Practical Control Technology (BPT). These are pollution abatement systems that are the average of the best for a particular type of industry. To establish BPT requirements, EPA surveyed facilities they considered superior in terms of wastewater control and mandated that all industries use technologies at least equivalent to those.

For the most toxic pollutants, Best Available Technology, or BAT, must be used. These can achieve the maximal, feasible pollution reduction for a given industry. In designating BAT, the EPA also considers nonpollutant reduction factors such as environmental impacts, energy requirements, and economic achievability.

The use of BCT, BPT, and BAT technologies applies only to wastewater discharges that were in operation prior to the passage of the CWA in 1972. More recent sources of wastewater discharges must comply with New Source Performance Standards (NSPS) requirements. These can be more stringent than BAT standards and require the installation of advanced and expensive wastewater treatment systems. They are designed to achieve the greatest reduction in pollutant concentrations possible, including the elimination of all pollutants from the waste stream. The need to comply with NSPS is hotly contested by many industrial facilities because these technologies often require major overhaul and upgrade of nonwastewater systems and can change entire production line operations.

Under the CWA, each state must establish water quality standards for its surface water bodies, and permits then are issued with those discharge limitations for pollutants. A practical example of these standards might be that to ensure trout propagation, there can be no more than 0.2 mg/L of arsenic in a certain river. Therefore, a state will not issue a NPDES permit that allows an industrial discharge into that river, taking into account dilution, mixing, and other natural attenuation factors, to exceed 0.2 mg/L. This concept is slowly being expanded into a watershedwide basis through the Total Maximum Daily Load (TMDL) part of the CWA.

TMDLs are quantitative limits on pollutants that can be discharged from all sources into a watershed.

TMDLs are established for the entire watershed and often require industrial facilities to meet even lower pollution discharge limitations. Under TMDL, if the state or EPA determines that the ecologically “safe” amount of arsenic for a given watershed is 3 mg per day, then all permit limits for industrial facilities discharging wastewater into that watershed will have their limits adjusted to the new standard. This means that a facility that had been allowed to discharge 0.2 mg/L of arsenic in 100,000 gallons (378,541 L) of wastewater per day, or 2.8 ounces (80 g) of total arsenic, may now only be permitted to release 0.002 mg/L of arsenic in that same volume of wastewater (0.03 ounces [0.8 g] of total arsenic), so that the total (TMDL) discharge of arsenic into the watershed river from all sources is 3 mg/day.

The CWA also establishes requirements and provides funding and technological advice for the control of storm-water discharges including runoff from city streets, parking lots, and industrial facilities that is diverted directly to a surface water body without treatment. In particular, this part of the act is intended to help municipalities address combined sewer overflows (CSOs) and sanitary sewer overflows (SSOs). In many older communities around the United States, the storm-water and sanitary sewer systems are combined into one. During a heavy rain, the city’s wastewater treatment system is often overwhelmed, and, to prevent flooding or damage to equipment, the operators must bypass the treatment plant and discharge raw sewage, mixed with rainwater, into the receiving stream or river. As these CSOs and SSOs move through the watershed, they can result in significant ecological impacts (e.g., fish kills) or threats to public health (bacterial infections).

Not all industrial discharges release their pollutants directly into “the Waters of the United States.” Many are connected to sewers that drain to municipal sewage treatment plants or publicly owned treatment works (POTWs). In this case, an industrial facility must first pretreat its wastewater to meet certain standards established for that particular industry. These pretreatment programs are intended to protect the integrity of POTW operations as well as the health and safety of their operators by making the industrial user remove or neutralize the most toxic or dangerous components of its process flow stream.

The CWA also created requirements for wetlands protection, coastal zone management, and dredging and filling of waterways. Facilities storing more than 1,320 gallons (5,000 L) of petroleum products that, in the event of a spill or some other catastrophic event, could reasonably be expected to enter a waterway must prepare and maintain a Spill Prevention,

Control and Countermeasure (SPCC) plan. This plan describes reporting procedures and cleanup of a release of oil that enters a water body or threatens to enter it.

### Objectives

The EPA and the states administering their own NPDES-equivalent programs can bring a variety of enforcement actions against those not complying with CWA requirements. An administrative order or directive can be issued for permit violations levying fines up to \$11,000 per day and requiring the discharger to achieve compliance within a specified time frame. For more serious violations of intentional discharge of pollutants in excess of permit limits, a civil action in federal court can be initiated. In this case, monetary penalties are much higher and cessation of all discharges can be ordered, effectively closing the business. Finally, for the most egregious violations of discharging toxic chemicals without a permit or failing to comply with administrative or court orders, criminal enforcement proceedings can be instituted and can result in personal fines and incarceration for the business owners or wastewater treatment plant operators.

The CWA also allows, under certain circumstances, any affected person to initiate his or her own enforcement action against an industrial discharger. These citizen suits typically are brought by environmental advocacy groups when the EPA or state agency is not “diligently prosecuting” a NPDES permit violation. Most of these suits are settled with monetary awards allocated to improve the discharge control technology or to support a local environmental restoration project of interest to the parties bringing the suit.

### SAFE DRINKING WATER ACT

In its most recently amended form (1996), the Safe Drinking Water Act (SDWA) continues its mission to protect the purity and safety of drinking water. The SDWA regulates private companies and utilities that find, treat, and distribute water to private homes and businesses. SDWA establishes a monitoring system designed to identify and control contaminants and to inform customers about the quality of the water they are drinking.

### Requirements

The SDWA applies to community water systems with 15 service connections used by year-round residents or that regularly serve at least 25 year-round residents. A noncommunity water system typically serves only a limited number of people for a short

duration such as a well in a recreational (campground) area that is only open during the summer. Homes or private residences supplied with water from a single well are not regulated under SDWA.

The SDWA establishes a set of water quality standards that must be met in order to remain in compliance. These standards are divided into National Primary and National Secondary limits. National Primary Drinking Water Regulations (NPDWR) include compounds known to have adverse effects on public health, and a Maximum Contaminant Level Goal (MCLG) is established for each of them. The MCLG is the level of a contaminant in drinking water below which there is no known or expected risk to health. MCLGs allow a margin of safety and are nonenforceable public health goals. They often are not economically or technologically achievable by water supply companies or utilities. For enforcement purposes, the EPA uses the compound’s MCL, or Maximum Contaminant Level. This is the highest concentration of a contaminant that is allowed in drinking water. MCLs are set as close to MCLGs as feasible on the basis of the best available treatment technology and taking cost into consideration. MCLs are enforceable standards.

If chlorine is used to disinfect water, a series of breakdown compounds can form (e.g., trihalomethanes). The amount of these compounds that is allowed in public water supplies is regulated by the Maximum Residual Disinfectant Level (MRDL), the highest level of a disinfectant allowed in drinking water. Obviously, the addition of a microbial disinfectant is necessary to control harmful bacteria, and the Maximum Residual Disinfectant Level Goal (MRDLG) is the level of a drinking water disinfectant below which there is no known or expected risk to health. The EPA is required by the SDWA to review the NPDWRs every six years to determine whether they need to be revised.

National Secondary Drinking Water Regulations identify compounds that do not pose a health risk at levels above Secondary Maximum Contaminant Levels (SMCLs) but may cause water users to experience adverse aesthetic effects. The water may appear discolored or have an unpleasant taste or odor. SMCLs are not enforceable standards under federal law but have been established as generic guidelines to help water purveyors assess the overall quality of their product.

SDWA regulations require that the water supplier provide annual reports to its customers with a consumer confidence report. This report describes the quality of the water delivered and characterizes risks related to exposure from contaminants present in the water. For example, if a water utility

or company detects radon at concentrations above NPDWR MCLs, the consumer confidence report must describe the associated risks and health consequences related to ingestion of those amounts as well as the actions of the supplier to restore water quality to compliance with MCLs.

The SDWA gives the EPA or state the authority either to take over or to shut down a water purveyor not only for documented violations, but also if the supplier is acting in a manner that may threaten or put at risk the health of its customers. Similarly, private citizens can bring an enforcement action if the regulatory agencies are not diligently requiring compliance with SDWA regulations.

Water suppliers are required to utilize Best Available Technology (BAT) for each NPDWR. Not all systems, however, have the financial or technical ability to implement each BAT technology. Under SDWA, the EPA can issue variances and exemptions for a NPDWR. These allow the company or utility to continue to supply water, even though it may contain contaminants above MCLs. Both variances and exemptions, which can only be issued if there is no unreasonable risk to the public, are not permanent and are intended to provide time for the supplier to upgrade and bring its system into compliance with SDWA regulations.

### Objectives

The SDWA provides funds for a revolving loan system to help small water suppliers (those serving fewer than 10,000 customers) to finance technological and water distribution improvements. Companies providing bottled water also must conform to most SDWA regulations, including periodic sampling to demonstrate compliance with MCLs. One unintended consequence of the SDWA is that water purveyors are becoming bigger. Smaller systems generally are not able to afford the improvements and upgrades periodically required to their treatment systems. Smaller community based systems are being merged or acquired by larger, nationally or regionally based companies that can spread those costs over a much larger rate base.

## RESOURCE CONSERVATION AND RECOVERY ACT (RCRA)

The Resource Conservation and Recovery Act (RCRA) became law in 1976 and was modified in 1984 by the Hazardous and Solid Waste Amendments (HSWA). Both pieces of legislation are focused on managing and ensuring the safe, environmentally appropriate disposal of the more than 50 million tons (45 million metric tons) of hazardous solid

waste generated annually within the United States. RCRA/HSWA mandates that producers of hazardous waste provide “cradle to grave” care of the material to prevent its unintentional release or unauthorized disposal.

### Requirements

Divided into 10 subtitles (labeled A through J), RCRA begins by establishing two definitions of what a hazardous waste is. Hazardous substances are those that cause or result in an increase in mortality rate or serious irreversible or incapacitating illness to people or represent a substantial present or future threat to human health or the environment if they are not managed and disposed of properly. A waste, that industrial residue that has no economic or recycling value or will not be reused in another manufacturing process, is considered hazardous if it (a) has certain characteristics of reactivity (violent instability in the presence of water or other chemicals), ignitability (low flash point), corrosivity (very low or very high pH), or toxicity that makes it inherently unsafe to handle or dispose of in a landfill; or (b) has been included in a series of lists developed by the EPA of waste compounds that the agency has determined to be hazardous by their very nature. The EPA has published a series of tables, the parameters against which a waste is tested to determine whether it is hazardous by characteristic. One example is that of “listed” hazardous wastes, those found by the EPA to be hazardous on the basis of the manufacturing processes that produced them.

Under RCRA’s Mixture Rule, if a hazardous and a nonhazardous waste are combined, the resulting product is considered hazardous. This rule was included to prevent industrial facilities from taking their hazardous waste, mixing it with plant trash or other debris, and disposing of it for much less money as nonhazardous waste. If a company generates hazardous waste, it must notify the EPA and describe the type and amount of waste material it is producing. The EPA then adds the company to its national database and issues it a hazardous waste generators number. Generators of hazardous waste are allowed to accumulate the material on site in special secure storage areas, but the hazardous waste must be disposed of at least once every 90 days. The storage areas must meet certain standards for, among other things, aisle space, inspection frequency, spill containment and control, and separation of incompatible wastes that might react violently if accidentally mixed together. Generators can either be small, producing 45–455 pounds (100–1,000 kg) per month, or large, producing more than 455 pounds (1,000

kg) per month. Each category of generator must comply with a specific set of waste-management and record-keeping provisions.

When disposing of the waste, a generator completes a shipping form called a Uniform Hazardous Waste Manifest. This form accompanies the waste from its point of origin to its point of disposal. Every time the waste changes hands, the manifest is signed, and eventually, upon arrival at the disposal facility, a completed manifest is returned to the generator and one copy is sent to either the EPA or the state regulatory agency. The use of the manifest ensures accountability for the hazardous waste and prevents unauthorized disposal. If a generator does not receive a copy of the manifest signed by the disposal facility within 15 days of waste shipment, the generator is required to file an Exception Report, notifying the EPA and/or the state agency that the hazardous waste shipment is unaccounted for. The EPA and/or the state agency then begins an investigation to determine the status of the material.

Trucking companies that transport hazardous waste to disposal facilities must also register with EPA and federal and state departments of transportation (DOTs). They operate primarily under a set of regulations issued and enforced by the DOTs, the Hazardous Materials Transportation Act (HMTA). This act and its related regulations regulate the types of containers to be used in shipping hazardous wastes, shipping method (rail, air, etc.), container labeling, as well as many other requirements.

Those facilities that either treat their own hazardous wastes on site or receive hazardous wastes from others for storage longer than 90 days are called TSD (treatment, storage, and disposal) facilities. TSDs are subject to very stringent regulatory oversight by EPA and state environmental agencies. TSDs can be landfills, surface lagoons, incinerators, or liquid/solid stabilization and treatment plants.

Under RCRA/HSWA, TSDs are required to obtain a permit to operate before they accept any wastes. Each facility must contain security systems to prevent accidental or unauthorized access to waste storage or processing areas, have provisions for regular inspections of waste handling areas, provide medical monitoring and appropriate training to employees in hazardous waste management procedures, and have an internal alarm as well as fire, spill control, and decontamination equipment on-site. TSD facilities in environmentally sensitive areas must comply with other special standards established for operations in those types of settings to reduce the risk of catastrophic equipment or process failure.

Hazardous waste incinerators must meet all Clean Air Act requirements, particularly those involving

the use of MACT. They must have continuous monitoring and automatic shut-down controls and be capable of achieving destruction and removal efficiency (DRE) of at least 99.99 percent.

RCRA/HSWA regulations mandate that TSDs reserve enough money with a third party so that the facility can be properly closed. This “financial assurance” is used to remove any hazardous waste left on the premises and decontaminant equipment. The funds also must be sufficient for 30 years of postclosure monitoring and maintenance, if TSD activities involved permanent, land-based disposal of wastes. Hazardous wastes must be qualified under the Land Disposal Restriction (LDR) program of RCRA/HSWA before being placed in a landfill, surface impoundment, or similar land-based disposal unit. LDR requires that liquid hazardous wastes or hazardous wastes that may leach hazardous constituents into the soil or groundwater be stabilized and tested prior to disposal. Results of this testing need to demonstrate that the toxicity of the wastes has been reduced and that the likelihood of waste migration from the disposal unit has been minimized.

LDR also requires the placement of wastes in specially designed disposal cells that have double plastic or clay liners, separated by a sand layer that captures liquids and sends them to a leachate collection system. Landfills and waste piles also must be finished with high-integrity clay or plastic caps covered with layers of crushed stone and topsoil that reduce infiltration of precipitation, minimize erosion, and prevent intrusion into the waste by burrowing animals. Gas venting and collection systems typically are incorporated into cap design, depending upon the type of waste being placed into the disposal unit. A series of monitoring wells are installed around the outside of the landfill or waste pile, and groundwater samples from them are tested on a regular basis to determine whether wastes or waste constituents are escaping from the disposal unit. If a release is detected, the TSD must perform Corrective Action.

Corrective Action is the part of RCRA/HSWA that requires a TSD facility to investigate and remediate releases from their solid waste disposal (management) units, or SWMUs. This is done through a RCRA Facility Investigation, or RFI. The RFI process investigates the placement of wastes in the SWMU, collects soil and groundwater samples in and around the SWMU, and identifies the amount of escaped waste and where it has gone. A RCRA Corrective Measures Study, or CMS, is then performed to evaluate the best way to stop and clean up the release. Once EPA or the state agency reviews and evaluates the CMS, the final step is the Corrective Measures Implementation (CMI), where the remedial solution is designed and

implemented. Wastes generated from the remediation of a leaking SWMU are sometimes placed in a special type of landfill called a Corrective Action Management Unit (CAMU). Design standards for CAMUs are not as stringent as those for generated wastes but still require liners and other environmentally protective systems.

RCRA/HSWA regulates not only industrial or commercial hazardous waste materials but also a number of items that many people would not normally consider hazardous. These include:

- Universal Wastes are those that are widely manufactured and generated and include nickel-cadmium batteries, returned pesticides, mercury filled devices, and fluorescent bulbs. Generators of these wastes must use special packaging and labeling and dispose of them at authorized facilities.
- Outdated unused, used, or fired munitions called “unserviceable munitions” are regulated under EPA’s Military Munitions Rule (MMR) and include chemical warfare and riot control agents. MMR also covers non-military disposal activities (police and federal law-enforcement firing ranges, etc.).

Medical wastes, used or unused syringes, medical devices, and human tissue currently are not regulated by RCRA/HSWA. In 1988, in response to washing up of medical waste on beaches in several mid-Atlantic states, the EPA established a demonstration program that temporarily included medical wastes as part of RCRA/HSWA. That program ended in 1992 and has not been renewed.

Used oil from motor vehicles also is not covered by RCRA/HSWA regulations, if the oil is destined for recycling. The EPA has established standards for those facilities accepting used oil for recycling.

### Objectives

The intent of RCRA/HSWA is to reduce the amount of hazardous waste being generated in the United States by encouraging generators to use more environmentally safe alternatives and to seek alternatives to land disposal. RCRA/HSWA has also been extremely effective in imposing order and accountability in the waste management climate.

### Underground Storage Tanks

Subtitle I of RCRA/HSWA addresses the regulation of underground storage tanks (USTs). There are approximately 700,000 UST systems in the United States, and the EPA estimates that about one-third

of them have leaked or are leaking into the soil or groundwater. USTs have long been recognized as one of the most common sources of soil and groundwater pollution, and several billion dollars is spent annually on the cleanups associated with those releases.

A UST is defined as any tank with more than 10 percent of its volume located below ground including associated piping. Septic tanks, process flow-through tanks, or emergency spill control tanks are not USTs. Tanks with a storage capacity of less than 110 gallons (416.4 liters), farm or residential tanks holding less than 1,100 gallons (4,164 liters) of motor fuel, and tanks of any size used for the storage and on-site consumption of heating oil also are exempt. There are numerous other exemptions for specialty UST systems, including those holding hazardous waste, in basements or vaults, and those used in wastewater treatment.

An owner or operator of a UST system must register it with the EPA or equivalent state agency and ensure that the tank meets the following requirements:

- Overfill prevention—Many releases associated with USTs occur during refilling or transfer operations. New and existing tanks must have systems installed on them that automatically shut off flow when the tank is 95 percent full. These overfill protection devices are similar to those used at gas stations, where a sensor in the nozzle shuts off flow if back-pressure is sensed.
- Spill Prevention—Releases often occur when the fill pipe is detached from the top of the tank. Even the few drops to cupful of oil or gasoline that could discharge from the fill nozzle, if repeated over time, can result in significant soil or groundwater contamination. Catch basins around the fill port must be installed on USTs to recover residual or excess fluids released during filling operations.
- Leak Prevention—New USTs, and their piping systems, must be installed with leak prevention systems such as double walls or special linings or coatings. For metal tanks, this includes corrosion protection systems that prevent naturally occurring decay of the metal walls.
- Leak Detection—Subtitle I regulations require tank systems to have a device that alerts the owner or operator in the event of a leak. These can include an in-tank sen-

sensor that detects changes in inventory or the presence of water, an out-of-tank sensor that measures the occurrence of product fumes in adjacent soil, or a sensor between the walls of double-walled tanks. In some cases, monitoring wells are drilled around the UST and special sensors are installed that sound an alarm if the tank contents migrate into the well. Out-of-tank systems are not preferred, because by the time an alarm sounds, the release has already occurred.

If a release occurs, sometimes called a leaking underground storage tank (LUST), it must be reported to either the EPA or the agency approved by the EPA to oversee remedial activities. Typically, these activities include removing the UST from service, emptying it, locating the source of the release, either fixing or replacing the damaged tank or piping, and implementing soil and groundwater cleanup activities. For most UST releases, contaminated soil is excavated and shipped to an off-site disposal facility. Waste released from the tank is pumped from the groundwater, and monitoring wells are installed to measure the distance of migration. Depending upon the nature and extent of the contamination, active groundwater treatment may be required, or, in less severe, low-risk cases, only long-term monitoring may be necessary to demonstrate that contaminant concentrations are slowly decreasing. Many states have their own, more extensive specialized LUST release reporting and cleanup protocols and procedures and require that cleanup be performed by qualified and licensed professionals.

Federal UST regulations require facilities to maintain financial responsibility or assurance, usually an insurance policy that provides funds to clean up a release from a tank system. Financial assurance also compensates third parties if they are injured as a result of a tank release. The EPA and many states provide funds in the form of low-interest loans or grants from gasoline sales tax for the cleanup of releases from USTs where the responsible party is unable or unwilling to implement necessary tank closure or cleanup activities.

### **COMPREHENSIVE ENVIRONMENTAL RESPONSE COMPENSATION AND LIABILITY ACT (CERCLA)**

Signed into law by President Carter on December 11, 1980, and amended in 1986 by the Superfund Amendments and Reauthorization Act (SARA) and again in 2002 by the Small Business Liability Relief and Brownfields Revitalization Act, CERCLA/SARA represents the final major legislative initiative

to address environmental protection in the United States. RCRA/HSWA establishes requirements for active, operating facilities and businesses generating and managing hazardous wastes, and CERCLA/SARA does the same for abandoned or inactive sites where uncontrolled hazardous wastes pose an unacceptable risk to public health or the environment.

### **Requirements**

An important part of CERCLA/SARA was the establishment of funds through a tax on certain types of petroleum and chemical products to clean up abandoned waste sites. This funding source, supplemented by general tax revenue and nicknamed Superfund, provides the EPA with the resources needed for either enforcement actions against responsible parties or undertaking cleanup activities on its own. The term *Superfund* is sometimes used interchangeably with CERCLA/SARA. The Superfund tax expired in 1995, and Congress has not reauthorized it. The EPA has reduced funding for the cleanup of abandoned hazardous waste sites and now conducts removal and remedial actions at only very high priority facilities. An attempt to reauthorize the Superfund tax failed in 2004, and although it has been reintroduced several times, it has yet to be passed into law.

CERCLA/SARA is implemented within the framework of the National and Hazardous Substances Pollution Contingency Plan or, more simply, the National Contingency Plan, or NCP. The NCP establishes the procedures and protocols that must be followed by EPA and private parties conducting CERCLA/SARA-type investigations and remedial actions. The NCP dictates the procedures; the actual cleanup is directed by the EPA.

Another important aspect of NCP is that it establishes the National Priorities List, or NPL. This list, also known as the Superfund Site List, includes those places that the EPA has determined represent serious threats to public health and the environment. A site is placed on the NPL if it is appropriate, using such factors as the number of people a release from the facility could impact, the types and conditions of hazardous substances present, and the potential for those substances to contaminate drinking water supplies or the air. Only those sites listed on the NPL qualify for funding of long-term remedial actions under Superfund. States can nominate sites for inclusion on the NPL to obtain money for cleanup, while companies that have facilities nominated for the NPL hotly contest the listing to avoid the stigma and to maintain greater flexibility in planning and implementing a remedial action.

A site is placed on the NPL subsequent to publication in the Federal Register and after a public

review and comment period. The EPA then contacts all companies that may have sent waste to the site for disposal or had an ownership interest in the facility. This list can number in the hundreds of companies, which are called Potentially Responsible Parties (PRPs). Under CERCLA/SARA, PRPs are liable (jointly and severally liable for the contamination on the property. The EPA may recover the full cost of the cleanup from any company that contributed waste or was involved in the ownership or active management of the site, regardless of what percentage of waste or interest the company had. Even if a company contributed 1 percent of the waste at a site, it can be required to pay up to 100 percent of the cleanup. Supporters of this rule contend that it protects the government from being undercompensated if one company cannot pay its share of the cleanup costs. It also makes enforcement proceedings easier because the EPA is not required to decipher how much a PRP contributed to the contamination at a site. Critics of the rule argue that it is unfair to PRPs with minor contributions. It encourages the EPA to find larger companies and has resulted in extensive litigation by PRPs trying to avoid paying for cleanups costs, which can be in the tens of millions of dollars for some sites.

Once the PRPs have been identified, the EPA may elect to negotiate with them to perform the required remedial actions, or EPA may proceed with the cleanup and attempt to recover the Superfund money through a CERCLA/SARA cost recovery action. If successful, the EPA cost recovery actions typically are for three times the amount of the actual cleanup and are intended to provide a strong incentive for PRPs to work together and implement needed remedial actions at the site.

The site investigation process follows steps described in the NCP. The first part of the process is the Remedial Investigation, or RI, which identifies the nature and extent of the contamination. Samples of waste, soil, groundwater, sediment, surface water, building materials, and air are analyzed to determine the locations and concentrations of waste or waste constituents. These data are used in a risk assessment to prioritize remedial actions. Upon completion of the RI, a Feasibility Study, or FS, is carried out. The objective of an FS is to evaluate both short- and long-term remedial options and to select the most appropriate one for the site. Remedial alternatives are compared against a number of criteria including long-term effectiveness, implementability, public acceptability, and cost. Often the RI and FS are done consecutively, and the EPA is presented with a single RI/FS study.

Upon review of the RI/FS, the EPA selects the final remedial action for the site and publishes its decision, along with supporting rationale, in a document called a Record of Decision, or ROD. The ROD summarizes the history of the site, the investigations performed, and the remedial actions considered during the FS. It also describes the public outreach carried out during the process and contains an account of the EPA decision-making process for the remedial alternative. After the ROD is published, the final remedial solution is implemented. If no financially solvent PRPs have been identified for a site, final remediation is dependent upon the availability of funding.

At some sites, a simple removal action is all that is needed to remediate it. In these situations, the site does not have to be added to the NPL for the EPA to commit Superfund monies. These are called limited response actions and generally occur in sites where the value of the remedial action is less than \$2 million.

### Objectives

Recent changes to CERCLA/SARA have created a class of PRPs that may be exempt from cleanup liability. These are innocent owners, purchasers of a property who conducted all appropriate inquiry for pollution when they acquired the site. If contamination is later found on the property, the new owner will not have to clean it up, if they do nothing to make it worse and cooperate fully with regulatory agencies. Similarly, adjacent property owners cannot be held liable for cleanup costs related to contamination that migrated onto their land.

## EMERGENCY PLANNING AND COMMUNITY RIGHT-TO-KNOW ACT (EPCRA)

Included as part of the 1986 Superfund Act Reauthorization Amendments (SARA), EPCRA requires certain businesses to submit information about the hazardous chemicals on their property to the EPA. This requirement was mandated to allow public access to information concerning hazardous chemicals in a community and to encourage the development of local emergency response plans. It also provides a strong incentive for businesses to phase out the use of hazardous substances to obviate any reporting requirements.

### Requirements

Local Emergency Planning Committees (LEPC) are named by states to review EPCRA information and develop plans to deal with a release of hazardous materials into the environment. Extremely Hazard-

ous Substances are chemicals covered by EPCRA including those with inherently acute and chronic toxicity, reactivity, or volatility that could cause serious irreversible health effects in the event of an accidental release. If a business stores or uses more than certain threshold quantities of ECRA substances, ranging from a few pounds to more than 500 pounds (227 kg), it must file the appropriate notifications. Reporting threshold quantities for other hazardous chemicals are much higher, ranging up to 10,000 pounds (4,545 kg) for some substances.

The quantities and in-plant locations of the hazardous substances are compiled and reported using either a tier I or a tier II inventory form. Tier I reports provide information on the maximal and average daily amounts of hazardous chemicals in use at the facility. If the LEPC requests additional, chemical-specific information, then a tier II report is filed describing the form of the hazardous substance, its health and physical hazards, and how it is stored and handled. Recently, transmittal of tier I and tier II forms is done electronically in software developed by the EPA so data can be forwarded to LEPCs without the need for extensive reformatting.

Certain facilities also are required to report the release of selected toxic chemicals into the environment. This reporting is not just limited to accidental spills or releases; it also includes those associated with permitted discharges from wastewater treatment plants, shipped to off-site disposal facilities, or emitted to the air through permitted stacks and vents. These releases are reported on a Form R and are available for public review.

### Objectives

EPCRA reporting requirements are viewed as potentially infringing on trade secrets or other types of proprietary manufacturing processes by many companies. LEPCs have antiterrorist concerns over making widely available the location and quantities of Extremely Hazardous Substances at a specific plant. EPCRA, however, has been very effective in alerting communities to risks associated with industrial activity around them and in having businesses reevaluate their need for hazardous chemicals.

### OTHER ENVIRONMENTAL LAWS

Although not as far-reaching or universal as RCRA or CERCLA or NEPA, there are several other supporting pieces of important environmental legislation. These laws, and their associated regulations, have been promulgated to address specific environmental or perceived public health risks that were not being adequately addressed. They include:

- Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) was passed in 1947 and amended repeatedly through the 1970s, 1980s, and 1990s. It requires registration of pesticides with the EPA and labeling about use and potential health effects. FIFRA's jurisdiction overlaps with that of the Occupational Safety and Health Administration (OSHA) in worker exposure issues and the Food and Drug Administration in residues on food or other consumer products. Registration applications require the manufacturer to provide extensive toxicological and environmental information about its product and, if approved by EPA, are only valid for a limited time. FIFRA also requires that most pesticides can only be sold to and used by or under the supervision of a certified applicator. Also, EPA has authority to cancel the registration of any pesticide and have it removed from the market if it finds that the product represents an imminent hazard to people or the environment. Unlike many other environmental statutes, FIFRA is almost solely administered by the EPA with very little delegation of authority to the states.
  - Oil Pollution Act (OPA) was passed in 1990, shortly after the *Exxon Valdez* spill. The OPA assigns liability for spills to the owners and operators of vessels or shore facilities, without regard to fault. This means that even if the release was not caused by the actions of the vessel's crew or staff, its owner and operators must pay for cleanup and related damages. Damage includes injury to property, injury to natural resources (birds, fish, etc.), lost revenue or taxes (tourism, fishing, etc.), and loss of public services. OPA limits the liability of a responsible party for removal and cleanup costs to specified amounts, depending upon the size of the vessel involved in a spill. Examples include a \$2 million limit of liability for vessels less than 3,000 tons (2,722 metric tons) or \$10 million for vessels larger than 3,000 tons (2,722 metric tons). For onshore facilities and deepwater ports, the limit of liability is \$350 million. Gross negligence or intentional malfeasance, however, removes those protective liability caps.
- If the cost of the spill exceeds the limit of liability, the responsible party can make a claim to the Oil Spill Liability Trust Fund,

which was established as part of OPA. Funded by a tax on imported oil, the now \$1-billion-plus fund is administered by the U.S. Coast Guard and is used to pay for both emergency response actions and longer-term cleanup activities, including compensation to third parties. OPA requires that all vessels operating within the U.S. territorial waters participate in mandatory drug and alcohol testing programs and that tankers be double hulled by 2015.

- Toxic Substances Control Act (TSCA) was passed in 1976 and amended three times since. TSCA requires manufacturers of chemicals to provide information on the health and environmental effects of their products and chemical mixtures and authorizes the EPA to regulate the formulation, distribution, use, and disposal of these materials. The EPA reviews information on new chemicals before they are manufactured and requires testing of new or modified chemicals that may present a significant risk to human health or the environment. If the EPA finds that the risks of the new or modified substance are not outweighed by their potential benefit in commerce, then they can ban its manufacture and distribution, including import and export of the chemical.

Under TSCA, the EPA compiles and updates an inventory of chemical substances manufactured or used in the United States. This list, known as the TSCA Inventory, contains information on the health and environmental effects of hundreds of thousands of chemical substances and mixtures used for commercial purposes as well as genetically engineered organisms. TSCA also regulates the use of existing chemicals that present a risk to health or the environment. These include asbestos, which was banned in 1989 by TSCA, as well as PCBs.

- Occupational Safety and Health Act was passed in 1970 and established the Occupational Safety and Health Administration (OSHA), which is responsible for safety and health in the workplace. Although not an environmental agency, OSHA regulates worker exposure to many different chemicals that also often are released to the environment. OSHA also sets exposure standards called Permissible Exposure Limits (PELs) for certain chemicals, and they are

used regularly as the basis for environmental and public health risk assessments.

OSHA also regulates companies generating hazardous waste or using hazardous chemicals and requires that they develop a hazardous communication (hazcom) program for their employees. Hazcom describes possible exposure risks and includes container labeling and posting of warning signs in appropriate chemical processing or waste storage areas. The centerpiece of OSHA's hazcom requirement is the Material Safety Data Sheet, or MSDS. This data sheet describes the physical and chemical properties of a substance and includes information on its potential health and environmental risks. The MSDS is intended to alert workers and emergency responders to the precautions and protocols to deal safely with a release of the substance.

**Erika oil spill Brittany, France December 12, 1999** *Water Pollution* Built in 1975, the *Erika* was an oil tanker registered in Malta and owned by Tevere Shipping, a Greek shipping company. It was built at the Kasado Dock Co. in Japan, one of eight similar ships that were intended to be sold as smaller (slightly less than 600 feet, or 183 m, long), inexpensive alternatives to the massive supertankers that were regularly transporting oil from the Middle East to Europe and the Americas. After many years of uneventful service, the useful life of the *Erika* was coming to a close. Almost 30 years old and not very sturdily built, by 1999, the *Erika* was serving the low end of the shipping market. It was cheap to charter and, according to a recent inspection by Registro Italiano Navale e Aeronautico, or the Italian Register of Ships and Aircrafts (RINA), it was still seaworthy.

RINA, a nonprofit organization, was founded in 1861 in Genoa, Italy, and is one of 10 international organizations that issue “class certification” documents. These confirm or validate that the certified vessel has been designed, built, and maintained in accordance with certain maritime standards and can be used for the intended purpose, which, in the case of the *Erika*, was the transport of oil. Certification requires that RINA conducts inspections during a ship’s construction and periodically during its operational life, including routine checks on an annual basis and more comprehensive inspections every five years. Inspection frequency increases as the ship ages. Without RINA or an equivalent certification, the vessel could not obtain insurance; nor would it be allowed to pick up or unload cargo in most ports. In summer 1998, the *Erika* successfully passed its five-year RINA inspection and underwent a major overhaul and repair in dry dock, including an inspection of its structural integrity. Throughout 1999, the aging tanker had been inspected 11 times and in each case had received an acceptable rating.

### THE ACCIDENT AND SPILL

On December 8, 1999, almost 31,000 tons (28,123 metric tons) of no. 2 fuel oil was loaded onto the *Erika* from an oil storage terminal in Dunkirk, the third largest port in France and a vital industrial center. The *Erika* was bound for a power plant owned by Italy’s most important electric utility, Ente Nazionale per l’energia Elettrica (ENEL). The fuel

oil was to be burned to make steam to turn the turbines connected to the generators needed to produce electricity. The oil in the *Erika*’s hold was owned by the charter company, Total Group, the world’s fourth largest oil and gas company. Formed by the merger of Petrofina (a Flemish oil company) and two French oil and chemical companies, Total and Elf Aquitaine, Total Group today is similar in size to Shell, BP, and ExxonMobil Corporations.

After performing its own evaluation of the ship, called a vetting, which primarily is a review and examination of inspection and maintenance records provided by the vessel’s owner and RINA, Total Group was satisfied with their choice to charter the *Erika*. At very low rates, Total Group would be able to deliver its oil safely and inexpensively and make a nice profit on this much-needed wintertime commodity.

Sailing from Dunkirk and into the Bay of Biscay, the *Erika* encountered a major winter storm. Battling 20-foot (6-m) waves and 60-mile-per-hour (96.6-km/h) winds, the ship made slow progress toward Italy. At about 2:00 p.m. on December 11, the ship’s master sent a telex distress signal to CROSS, the Regional Rescue and Surveillance Center, equivalent to the U.S. Coast Guard. CROSS centers manage, direct, and perform rescue efforts as well as control navigation and fishing activities in French waters.

The telex message sent by the *Erika* to CROSS informed them that the ship was listing to starboard by about 10 degrees, gave the position of the vessel, but indicated that the list was under control and that no immediate assistance was required. The crew was attempting to correct the list, or rebalance the ship, by pumping ballast water from one section of the hull to another. The captain later cancelled the distress call and advised CROSS that he would submit a more complete report on the situation at a later time. At around 6:30 that evening, which was a Saturday, the ship captain called Total Group headquarters and left a voicemail message informing them that the weather was too severe to continue on the planned course and that he was turning toward the French coast to seek shelter until the storm dissipated. As the *Erika* sailed within 45 miles (70 km) of Brittany’s Finistère Peninsula, the crew reported that there was a crack in the main decking plates that extended across almost the entire width of the vessel.

At around 6:00 a.m. on Sunday, December 12, the captain issued a second distress call to CROSS, warning that the ship “had very serious structural problems” and requesting that he and his crew be evacuated immediately. When French CROSS and British navy helicopters arrived, they found the *Erika* in two pieces about a quarter-mile (0.4 km) apart.

The stern of the tanker *Erika* sinks after breaking up off the Brittany coast, France, December 13, 1999. (AP Images)

Oil was in the water. Fighting gale-force winds and very rough seas, they winched to safety the 26-person crew from the now separated and drifting wreck.

Twelve days later, on December 24, driven westward by more winter storms, the cargo oil spilled from the *Erika* reached and began to spread along the French Atlantic coastline. Eventually, the oil washed up along a 250-mile (400-km) stretch of beaches between the Finistère and Charente-Maritime, one of the major vacation destinations for European tourists in France. Later estimates concluded that of the almost 34,200 tons (31,000 metric tons) of fuel oil on the *Erika*, about one-third (11,000 tons, or 10,000 metric tons) washed up on the shore.

### CLEANUP AND IMPACT

The impact of this oil spill was severe, despite the efforts of 800 soldiers and countless paid laborers and volunteers to recover the oil and minimize its ecological damage. The carcasses of 21,000 oil-covered, dead, or dying seabirds, mostly guillemots, puffins, gannets, and kittiwakes, were found during the cleanup effort, and Brittany's Society for the Study and Protection of Nature estimated that another

80,000 were likely to die. Once coated with oil, the birds tried to preen, or use their beaks to scrape the hydrocarbon off their feathers. This resulted in ingestion of the oil and their eventual poisoning. Many birds were captured and airlifted to a special cleaning and treatment facility in England but did not survive the trauma or succumbed to hypothermia as the natural, protective oils that coated and insulated their feathers was stripped off, either by the *Erika's* oil or by detergents used to clean them.

Bulldozers, excavators, shovels, and rakes were used to collect 297,600 tons (270,000 metric tons) of oily sand and debris off the beaches. This material was taken to a nearby Total Group oil refinery in Donges, France, for recovery and recycling or disposal. Tourism dropped by 85 percent that year, and the offshore oyster and mussel beds, a source of much-needed revenue for many local residents, were destroyed. Fishery resources were not as exposed to the oil and not significantly impacted. Oil collection and beach restoration continued until midyear 2003, with the last of the oily debris treated at Donges in 2004.

The severe weather minimized the effectiveness of floating oil recovery operations at the offshore

wreck of the *Erika*. Only an estimated 1,100 tons (1,000 metric tons) of oil was recovered by skimmers and booms. The two pieces of the *Erika* continued to drift, and, on December 13 as French authorities attempted to tow the stern section farther out to sea, it sank. The forward section had gone down earlier. Both sections of the ship contained an estimated 12,100 tons (11,000 metric tons) of oil and were now resting on the bottom of the ocean in some 400 feet (122 m) of water just 40 miles (64.4 km) south of the Brittany coastline. Obviously, so much oil so close to one of the most important tourist centers and ecological habitats in France could not be allowed to remain in place. The threat from ongoing leakage was too great. Total Group responded by using recently developed remote robot technology, eventually sealing the hulls and, by September 2000, recovering almost all of the 12,200 tons (11,000 metric tons) of oil from the two derelict pieces of the sunken hulls. The remaining 9,000 gallons (34,070 L) of oil released by the *Erika* when it sank is thought to have been either biodegraded or dispersed within the ocean.

### THE AFTERMATH

Investigations by RINA, Total Group, and the French government generally seem to agree that the probable cause for the *Erika* disaster was that the vessel's internal structural system failed and that this failure probably was related to repairs to the ballast tanks performed in 1997. RINA had inspected and approved these repairs at the time they were being done. As experts appointed by the Dunkirk Commercial Court concluded, "the true condition of the vessel's structures was not consistent with the certification issued by RINA." The report also raised questions as to whether these and other repairs actually were carried out. These same experts further found that the severe weather contributed to the *Erika*'s sinking, but that by themselves, the rough seas and high winds should not have caused the ship to go down.

Liability for damages associated with the sinking, including the cleanup, ecological destruction, loss of the ship and its cargo, and economic impacts from missed tourism, are still being adjudicated. The vessel's owner claims that RINA is to blame and has refused to accept responsibility for the damage the oil spill has caused. RINA admits to some responsibility for the failure of the ship but states that the owner was ultimately responsible for the maintenance and safe operation of the vessel. Total Group has claimed that it could not have known about the poor condition of the vessel and that it relied on

information provided by RINA and the ship's owner during its vetting process.

Total Group has reserved almost \$270 million to pay for the cleanup and settle claims made by injured parties. The International Oil Pollution Compensation (IOPC) fund has settled 5,600 private party claims for almost \$158.4 million and is still in negotiations over another 1,300 claims. IOPC also paid the French government \$53.8 million for the costs of the cleanup and is expected to settle the remaining governmental claims of almost \$200 million. In early 2007, the trial began in a Paris criminal court to determine final responsibility for the spill. Total Group, the owners of the oil, and the *Erika*'s charter company, is accused of pollution and deliberately failing to take the necessary measures to prevent the release of oil from the *Erika*. Fourteen other individuals and corporations, including four that participated in sea rescue and oil recovery operations, also are on trial, accused of similar charges. More than 60 plaintiffs, including the French government and three labor unions, are claiming damages.

In January 2008, a French court convicted the Total Group of maritime pollution and ordered the company and three other parties (RINA, the ship's owner, and the ship's operator) to pay \$285 million in compensation. Ten other defendants, including the ship's captain, were acquitted. The group is currently appealing the verdict.

**ethylbenzene** Ethylbenzene is part of the BTEX (benzene, toluene, ethylbenzene, xylene) component of fuel including gasoline, diesel, and jet fuel. Fuel leaks from gas stations or other fuel storage facilities, as well as spills during transportation, are probably the most common point source pollutants to groundwater systems in urban to suburban areas. Exhaust pipe emissions also contain ethylbenzene, providing a significant nonpoint source of pollution in the same areas. Although ethylbenzene may have limited industrial uses, its presence in fuel make it one of the most widespread pollutants. To illustrate how prevalent ethylbenzene is, it has been identified in 731 of the first 1,467 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List), which is among the highest percentages of any hazardous substance. It is largely for this reason that ethylbenzene is rated as the 99th most dangerous contaminant on the 2007 CERCLA Priority List of Hazardous Substances, which includes 275 entries. The properties and health effects of ethylbenzene make up the rest of the reasons for concern.

### PROPERTIES, USE, AND PRODUCTION

Ethylbenzene, also known as ethylbenzol and phenylethane, is an organic compound that is classified as a hydrocarbon. It is naturally occurring in crude oil and coal tar and occurs as a colorless liquid with a strong gasolinelike odor. As an industrial chemical, more than 99 percent of ethylbenzene is used to make the organic compound styrene, which, in turn, is used to make polystyrene and other plastics. The remaining ethylbenzene is used as a solvent for paints, stains, varnish, lacquers, rust preventative, adhesives, inks, and cleaning fluids, as well as in making rubber, dyes, perfumes, degreasers, pharmaceuticals, pesticides, and plastic wrap. Its main use, however, is in gasoline (about 2 percent by weight) and other fuels, as well as in tar and consequently creosote, asphalt, and naphtha-containing compounds. The production of ethylbenzene as an individual compound increased from 6.9 billion pounds (3.1 billion kg) in 1982 to 11.8 billion pounds (5.4 billion kg) in 1993 and more than 12 billion pounds (5.5 billion kg) by 1994.

### ENVIRONMENTAL RELEASE AND FATE

Not only is ethylbenzene widely released into the environment through its presence in fuel and other petroleum products, it has other nonpoint sources including tobacco smoke, wood smoke, incineration, power generation, and any internal combustion

engine. It is released as a point source pollutant from industrial emissions including spills and leaks during storage and transportation and improper disposal. Ethylbenzene is primarily released to air, because it evaporates easily. Even emissions to water and land contribute to the vapor content in the atmosphere. It degrades in air by photochemical reactions with hydroxyl radicals with a half-life rate of 0.5–2 days depending upon physical and chemical conditions. These by-products contribute to smog and may be removed back to the surface by precipitation. If released to surface water, most of the ethylbenzene will evaporate with a removal half-life of 3.1 hours for rapidly flowing water. That which does not evaporate will primarily undergo aerobic biodegradation and chemical reactions, though some may adhere to particles and settle into the sediment. In soil, the remaining ethylbenzene that does not evaporate is relatively mobile in most cases, binding only moderately to most soil particles though more strongly to clay and organic material. Leaching into groundwater is, therefore, common, especially around waste facilities. Once in groundwater, it will degrade in about eight days (10 days in seawater). Breakdown in soil and groundwater is primarily through biodegradation but also through chemical reactions depending upon condition.

The industrial release of non-fuel-related ethylbenzene as reported in the EPA Toxic Release Inventory from 1987 to 1993 was more than 761,000 pounds (345,909 kg), 94 percent of which was to land. The releases were primarily from petroleum refining and as such were far and away most common in Texas, followed distantly by the Virgin Islands, Illinois, Puerto Rico, Virginia, Delaware, New Jersey, New Mexico, Wyoming, and Louisiana. These industrial releases pale in comparison to its release as a component of fuel and in vehicle exhaust.

### HEALTH EFFECTS FROM EXPOSURE

Ethylbenzene is considered to be moderately toxic through both inhalation (the most common route) and ingestion. Acute exposure to ethylbenzene produces throat and eye irritation, excess salivation, tightening of the chest and labored breathing, and central nervous system effects such as fatigue, dizziness, and headache. In high doses, it has been shown to cause pulmonary effects, kidney and liver damage, and death at extreme dosage. Chronic exposure has caused damage to the blood, central nervous system effects, and kidney and liver damage. Ethylbenzene has also been shown to cause reproductive problems including increased incidence of fetal resorption and developmental problems such as

slowed skeletal growth and birth defects. The EPA classifies ethylbenzene in group D, not classifiable as to its potential as a human carcinogen. Several studies, however, have shown an increased incidence of kidney and testicular cancer in rats and lung, bronchial, thyroid gland, pituitary gland, and liver cancer to varying degrees in mice as the result of exposure to ethylbenzene.

### REGULATIONS ON HUMAN EXPOSURE

Worker and public exposure to ethylbenzene is regulated by several federal agencies; however, almost everyone is exposed to it in some form. The EPA limits ethylbenzene in drinking water to a maximum of 0.7 parts per million (ppm) under the Safe Drinking Water Act. They recommend a maximal exposure of 20 ppm for any one-day period, and for any longer periods it should not exceed 3 ppm. They also require the reporting of any spill of ethylbenzene of 1,000 pounds (454 kg) or more to the National Response Center in Washington, D.C. The Occupational Safety and Health Administration (OSHA) set a permissible exposure limit (PEL) of 1 ppm of ethylbenzene in workplace air over an eight-hour-day, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) set their exposure limit (REL) to the same level as OSHA but over a 10-hour day. They further set a short-term exposure limit (STEL) at 125 ppm for any 15-minute period and an immediately dangerous to life and health (IDLH) limit at 800 ppm.

**eutrophication** Virtually all surface water bodies in the United States are undergoing some degree of the complex process of eutrophication. In urban and agricultural areas, eutrophication is rampant and has radically impacted the ecology of water bodies. Many communities have taken steps to reduce the effects, but it is a losing battle and some of the methods risk further environmental degradation. More recently, eutrophication has begun to invade our coastal marine waters as well in the form of "dead zones." These features are more of a threat to the environment and even threaten human survival.

### THE PROCESS OF EUTROPHICATION

The basic cause of this eutrophication is overfertilization—the overabundance of nutrients in a water body that causes the algae and vegetation in the water to bloom. Reproduction, growth, and survival of individuals are greatly enhanced, and the water body turns green with growth. Such productivity might appear desirable as it provides more food and actually consumes carbon dioxide. These aquatic species, however, are short-lived, and the water soon becomes choked with plant mass. Bacteria, in turn, flourish with the abundance of food for them. The problem is that these bacteria consume oxygen in the water. As a result, hypoxic conditions develop in the water body. Many of the other organisms that inhabit the water body depend on oxygen in the water for their survival. They are either killed by the conditions or driven off, depending upon their mobility and whether the water body is closed or open. As a result, the body will have a reduced biodiversity, especially with regard to fish and aquatic invertebrates and in extreme conditions may become "dead" with respect to all animals. The loss of these organisms is progressive because different species have different tolerances for oxygen in the water. There are even some organisms such as jellyfish that are relatively unaffected by hypoxic conditions and can survive, even prosper, in water with low oxygen content.

### CAUSES OF EUTROPHICATION

Certainly, eutrophication is a process that occurs commonly in nature. Heavy rain or quick spring thaws can sweep nutrients from the terrestrial surface into a water body. A small response takes place, but natural processes regulate themselves relatively well in all but the most extreme of cases. The real problem with eutrophication results from anthropogenic input of nutrients into surface water.

The major cause of eutrophication is the overuse of fertilizers. By far, the chief source for the vast majority of the volume applied to surface water is agricultural. Although natural fertilizers such as manure can cause eutrophication, the greatest source is chemical fertilizers. As the population increases, there are greater demands on farmers to produce greater amounts of food, and the overuse of fertilizers can become rampant. There is no problem as long as the fertilizer remains on the field, but any rainstorm or even just a watering of the plants washes some of it into streams, ponds, and other surface water bodies. Small amounts of fertilizer can be absorbed into local ecological systems, but large

quantities overwhelm them, and the excess continues into ever larger streams, rivers, and lakes. It is by this process that eutrophication becomes epidemic.

For most of agricultural history, any excess nutrients that continued through river systems and emptied into a receiving ocean basin were quickly absorbed into the vast marine ecosystem. In the 1960s, however, a zone of eutrophication developed in the large Black Sea in the Soviet Union (USSR) as the result of heavy agricultural activity in the area. It was still thought by most that such an occurrence could only happen in a restricted body of water such as the Black Sea and under unusual conditions of heavy use of fertilizers. These hypoxic zones in marine waters were named dead zones because of the lack of marine organisms. These dead zones began to develop in many areas around the world where a major river flowed through an agricultural area. At the mouth of the Mississippi River, the dead zone in the Gulf of Mexico is the size of the state of New Jersey and one of the largest. By 2006, some 200 dead zones had been identified around the world.

Algae bloom off Coquina Beach, Florida, 2006 (AP Images)

**Cartoon diagram illustrating how eutrophication takes place in a stream. The left side shows a healthy stream with diverse fauna, abundant dissolved oxygen, and low biochemical oxygen demand (BOD). Input of sewage increases BOD, thereby reducing dissolved oxygen to conditions that can only support a poor and undesirable fauna. It takes quite a bit of natural attenuation of the sewage to restore the stream to healthy conditions. Input of fertilizers has the same effect.**

Agricultural fertilizer is not the only source for eutrophication. The quest for the perfect lawn in the suburbs also requires a heavy treatment of fertilizer. During precipitation events, surface runoff carries the excess nutrients from the lawns to storm drains and finally into streams and rivers or directly into the ocean, in the case of coastal communities. Eutrophication of bays, estuaries, and even the ocean is increasing in many areas of the United States. One of the better-developed dead zones occurs in the Chesapeake Bay of Maryland. There is some agricultural component to the nutrients, but coastal development has also been identified as a contributor. This coastal eutrophication is drastically reducing the productivity of coastal waters and may have dire consequences for the burgeoning human population on Earth.

Another source of nutrients in these coastal settings is overflow of septic systems. This was also the major cause of eutrophication of lakes and ponds in populated urban and suburban areas in the past. It may still be the case in some areas, but the building of new leak-proof, high-capacity sewer systems has reduced septic overflow in general. This issue was even addressed in a legislative manner in the 1970s to some degree. Clothes washing detergent used to contain phosphates. These phosphates had a strongly negative effect on ponds and streams to the point where they were restricted and banned from detergents as the result of public pressure and atten-

tion by the government (Congressional Report HR 92-918 March 15, 1972).

Air pollution fallout and washout by precipitation are other sources of eutrophication. Particulate can contain a significant amount of nitrogen compounds, and one of the six criteria air pollutants is nitrogen oxides. In the natural environment, these react to form nitrate, which is a strong fertilizer. As a result of this and other factors, there is a large diffuse halo of eutrophication in the waters around several cities that adds to the other factors.

### CONTROLS ON EUTROPHICATION

Besides the removal of phosphates from laundry detergent and even though eutrophication is globally recognized as a major environmental problem, the only controls that have been extended to eutrophication have been incidental. There are regulations on septic systems and sewer capacity and function that curb eutrophication but only as a collateral effect of controlling potential disease from poor sewage management. Air pollution controls and regulations attempt to limit the amount of nitrogen oxides in the air to control acid rain and tropospheric ozone with no thought to controlling eutrophication. The reality is that eutrophication is a widely recognized problem with dire consequences that threaten the very survival of humankind, and yet very little is being done about it.

**ex situ remediation of contaminated groundwater** Technologies related to the remediation of groundwater can be divided into those that require groundwater be extracted and brought to the surface (ex situ) and those that operate within the subsurface (in situ). Each has its advantages and disadvantages, and the selection of one technology versus another is largely dependent on such factors as contaminant type, site physiographic conditions, remedial program objectives, and costs. In this section, nine common ex situ approaches for the cleanup of contaminated groundwater are described.

#### **METHODS TO ESTABLISH HYDRAULIC CONTROL**

Groundwater, as does the surface water in streams and rivers, moves in response to changes in hydrostatic pressure. These changes can be driven by differences in recharge or infiltration rates, a variety of subsurface features, or even withdrawal of groundwater in other areas. For an ex situ remedial system to be effective, groundwater must be collected at a fairly predictable and steady rate, but the natural forces that influence groundwater movement are

often not reliable and steady. A number of recovery methods, therefore, are used to capture or divert contaminated groundwater into collection devices for transport to an ex situ treatment facility. The most commonly used ones include pump and treat; French drains or interceptor trenches; slurry walls; and phytohydraulics.

#### **Pump and Treat**

When groundwater is withdrawn from an aquifer, or water-bearing zone, by a pump installed in a well, it causes a lowering of the water table in the area around the well. The extent of this artificially lowered water table, if viewed in cross section, is called the pumping well's cone of depression and is dependent on such factors as:

1. pumping rate, or the amount of groundwater being withdrawn over time;
2. the amount of water the subsurface sediments hold, or specific capacity; and
3. the rate at which new groundwater can move through the subsurface to replace the groundwater that has been pumped out, or the transmissivity of the sediments.

If wells are aligned in a pattern such that their cones of depression overlap, they create an obstruction or barricade through which groundwater cannot pass. This method, called pump and treat, is a system of wells aligned to form a hydraulic barrier to collect contaminated groundwater for subsequent treatment and to prevent its migration to uncontaminated areas.

A significant shortcoming of pump and treat systems is a phenomenon called rebound. As the cone of depression forms, it draws down the water table and residual contamination may remain adsorbed to soil in this now unsaturated zone. At many sites, this area near the former top of the water table may be the most severely impacted. As contaminants are removed from the aquifer, and monitoring indicates that cleanup goals have been met, the pump and treat system is turned off. The water tables rise to their original (preremedial) levels and become recontaminated by constituents left untreated in the former cone of depression. When this occurs, pump and treat systems are operated in pulse mode, which means they are turned off and on repeatedly in an attempt to flush out the contaminants remaining in the cone of depression. This phenomenon can result in the need to operate a pump and treat system for many years, sometimes decades, as contaminants

stuck to the soil are slowly flushed off by the periodic rise and fall of the water table. In many cases, pump and treat systems are used only when other methods will not be as protective of public health, such as when a contaminant plume is moving toward wells that provide potable water to a large number of people or a municipality.

### French Drains

If the groundwater table is near the surface (usually within 20 feet, or 6.1 m) and is present in a soil with a relatively low permeability or hydraulic conductivity, another way to capture it is with a French drain, or interceptor trench. French drains have been used for years by homeowners and landscapers to remove excess water from low areas and other places where the soil tends to become saturated. Essentially they are trenches excavated deep enough to intersect the groundwater. The trench is filled with gravel and topped by a layer of sand. Usually, modern French drain designs include a perforated drainpipe to aid in water collection.

French drains are low cost and easy to install, they do not require electricity, and they can operate effectively for years with relatively little maintenance. They also can be covered over with asphalt or landscaping, making them easy to incorporate into site redevelopment plans. The French drain or drains are tied to a sump where the groundwater is collected and then pumped to a treatment system. This collection sump must be “intrinsically safe,” or fire and explosion resistant, if the groundwater being collected contains contaminants with explosive or highly flammable compounds.

### Slurry Walls

Also called diaphragm walls or cutoff walls, slurry walls are subsurface barriers consisting of vertically excavated trenches filled with clay slurry. The slurry, usually a mixture of bentonite (a type of clay that expands when wet), Portland cement, coal ash, and water, prevents the trench from collapsing during excavation and helps to slow groundwater flow. As the trench is deepened and keyed into or connected

**Diagram of a low-temperature thermal desorption system in which contaminated soil is fed into a rotary kiln and cooked at relatively low temperatures to vaporize and treat pollutants in several gas and particulate remediation systems.**

to a less permeable subsurface layer or even bedrock, assuming it has the right characteristics, the excavated soil is mixed with more bentonite and returned to the trench, where it hardens, creating an underground dam. As added protection, a layer of plastic is sometimes draped across the downgradient side of the trench to slow groundwater flow further or even prevent the migration of vapors that may be emanating from the contaminated groundwater. Slurry walls can be installed at depths up to 100 feet (30 m) and are generally two to four feet (0.6 to 1.2 m) thick.

### **Phytohdraulics**

Certain plants can be used to influence and, in certain settings, actually control the flow of groundwater. As a plant's roots penetrate the aquifer, they withdraw water to support their biological activities (growth, creation of cell mass, etc.). Phreatophytes are deep-rooting plants or trees that use groundwater as their main source of moisture. *Phreato* is from a Greek word that means "well or spring." Common examples of phreatophytes are the tamarisk (salt cedar) and willow. The ability of phreatophytes to withdraw large quantities of groundwater is well documented. Mature poplar trees use 25–50 gallons (95–190 L) of water per day, cottonwoods 50–350 gallons (190–1,323 L) per day. Willows are enormous water consumers, taking in and transpiring up to 1,300 gallons (4,914 L) per day; that is why they tend to grow in areas where the soil is saturated all year such as swamps and marshes. This uptake, consumption, and eventual transpiration of groundwater can help contain or reduce the migration of contaminants. Although they are very dependent on the type of vegetation, climate and growing season, soil type, and depth to water, the effective rooting depth can be as much as 30 feet (9.2 m) below the surface.

Phytohdraulics has been used in vegetated landfill caps and covers to reduce infiltration of precipitation and snowmelt and therefore minimize the amount of leachate production. The presence of vegetation also helps stabilize the soil and reduce erosion. If used in this way, the selected plants need to have shallow roots so they do not breach the cap or cover and penetrate the waste.

Another use of phytohdraulics is in the construction of buffer strips and riparian corridors. Buffer strips are planted downgradient of the contaminant source to intersect the contaminated plume in groundwater. In addition to helping to control the flow of groundwater, buffer strips offer an opportunity for the selected plants to degrade the contaminants in the groundwater through phytore-

mediation. If buffer strips or filter strips are planted along streams or drainage ditches, they are called riparian corridors and are used to control runoff of pesticides, sediment, and fertilizers from agricultural fields.

## **EX SITU REMEDIATION TECHNOLOGIES**

All of the ex situ technologies described have a number of common characteristics. Each requires a way to capture or control the subsurface migration or flow and recover the contaminated groundwater. In addition, each ex situ technology involves the use of an aboveground treatment facility or plant, which can sometimes be very expensive to build and operate. Finally, ex situ technologies have to include a way to manage the groundwater once it is recovered and treated. This can be done either by discharging it to a surface water body, reinjecting it into the subsurface, or using it in an industrial or commercial application such as cooling for a furnace or air conditioning system. The main advantage of these technologies is that the remedial process can be vigilantly monitored and controlled. The contaminated groundwater is delivered to a treatment plant that has been carefully engineered and is operated by trained and licensed professionals and been permitted by either federal or state regulatory agencies.

### **Air Stripping**

Air stripping is a process whereby recovered groundwater is exposed to or mixed with large quantities of air, causing separation of volatile organic compounds (VOCs) that may be dissolved in the groundwater. This partitioning process takes place because the VOCs have a low octanol-water partition coefficient ( $K_{OW}$ ), or ratio of the concentration of a chemical in octanol and water. The coefficient is measured in the laboratory and given at equilibrium and for a specified temperature. Contaminants with low  $K_{OW}$  are easily partitioned or stripped from the groundwater. Those with high  $K_{OW}$  must be remediated by using another approach. Contaminants such as heavy metals, polychlorinated biphenyls (PCBs), and pesticides cannot be treated by air stripping.

Air strippers spray the contaminated water down a column or stack as air is blown up through it. Inside the column is a packing material, usually plastic or metal baffles, that act to slow the downward flow of water and increase its contact time with the air. The separated VOC vapors are collected at the top of the column and either burned, run through a carbon filter, or distilled and collected for later disposal. The treated groundwater flows out the bottom

of the column and is either returned to the aquifer, or water bearing zone, to flush out additional contaminants or discharged to a sewer or surface water body. Properly designed, air strippers are effective at removing 99 percent of the VOCs from groundwater. The technology is relatively simple, and once the system is operating, it usually is only shut down for routine maintenance or cleaning or changing of the packing material. Electrical usage and operation of air blowers, however, are high, and the packing material is susceptible to fouling (calcium/magnesium scaling or growth of microorganisms). Treatment costs for collected VOCs are often expensive and can add significantly to overall system operation and maintenance expenses.

Collected groundwater usually is pumped to a holding tank, where silt and other debris can be settled out or separated pollutant can be skimmed off or collected. A holding tank also allows contaminated groundwater to be fed into the air stripper at a constant rate. This helps ensure efficient system operation and reliable treatment. Types of air strippers include structured and random packed towers, sieve and diffused chamber trays, and diffuse aerators.

### Bioreactors

Another way to treat contaminated groundwater that has been pumped out of an aquifer, or water-bearing zone, is through the use of a bioreactor. In a bioreactor, microorganisms are allowed to mix or have contact with groundwater and degrade the contaminants by using them as a source of energy. Air and nutrients are added to the groundwater to encourage and sustain microorganism growth. Bacteria are the primary microorganisms responsible for destroying the contamination. Protozoa and rotifers are used to scavenge stray bacteria that try to leave the system.

Bioreactors work only when the contaminants dissolved in the groundwater can be useful as an energy source for the microorganisms. The contaminants must contain carbon that the bacteria can consume relatively easily. They work best for petroleum hydrocarbons and some types of chlorinated solvents. Bioreactors cannot easily treat groundwater with such contaminants as heavy metals, radionuclides, and complex organic chemicals such as pesticides and PCBs. There are two basic types of bioreactors: attached (fixed film) or suspended biological systems.

In attached, or fixed film, bioreactors, an inert medium or structure is provided for the growth of the bacteria. As the contaminated groundwater flows through or across the medium, the bacteria

attack the contaminants, breaking down the organic chemicals to use the carbon as an energy source. The microbial population is derived from natural selection within the reactor or can be borrowed from another bioreactor. As the bacteria grow, they slough or fall off and settle to the bottom of the chamber and are removed during routine maintenance. A trickling filter, where the water is distributed over the top of the growth medium, is a type of fixed-film bioreactor. Eventually, with most of the contaminants removed, the groundwater is sent to a clarifier, where any remaining particulate settles. The water then is tested and discharged.

Suspended growth systems use an open chamber and stirring paddles to mix the microorganisms with the contaminated groundwater. As individual bacteria grow by feeding off the carbon contained in the oil or solvents as their energy or food source, they clump together in a process called flocculation. As the biological floc grows, it becomes heavier and sinks to the bottom of the tank, forming sludge. This sludge layer is periodically removed or sometimes reused in the treatment process. Treated groundwater is sent to a clarifier and then either discharged or recirculated through the buried waste. Some suspended growth systems add minute particles of sand grains, bits of coal or carbon, even chemical gels that bacteria can attach to while they float in the tank. These types of systems are called fluidized bed reactors.

Both types of bioreactors can be combined into a single system called a rotating biological contactor, or RBC. In this system, microorganisms are established on a series of disks mounted on a common shaft or axle. These disks are rotated slowly to move into and out of the contaminated water. As the bacteria grow, they fall off the disk but are kept in suspension by the rotation of the disks to aid in the treatment of groundwater present in the chamber. As groundwater is cleaned, it flows to a clarifier for testing and discharge or waste mass infiltration. Bacterial sludge is removed as necessary from the bottom of the RBC.

Bioreactors are most effective when designed to treat large volumes of contaminated groundwater over long periods. They are especially useful if the contaminant must be destroyed and not simply transferred to another medium as occurs during air stripping. Bioreactors also have limitations. They are difficult to balance, and the microbial populations can be killed off if contaminant concentrations are too high or if nondegrading microorganisms dominate. Low air temperatures can interfere with system performance, and the residual biomass that occurs as the sludge that accumulates in the bottom of the

tank may require special or additional treatment prior to its disposal.

### **PRECIPITATION OF POLLUTANTS**

The treatment technologies described are those effective at removing dissolved organic compounds from groundwater. For metals and radionuclides present in groundwater, the process is more complex. Metals dissolved in groundwater usually occur as soluble salts including nitrates, chlorides, and sulfates such as silver nitrate, barium sulfate, or mercury chloride, among others. The objective of a precipitation treatment process is to convert the soluble metal salt into an insoluble salt that can then be physically removed by filtering or settling from treated water.

Hydroxide precipitation is the most common way of removing metals from wastewater. Hydroxide is a compound that contains an oxide joined with water. To form hydroxides and, thus, cause metals dissolved in groundwater to precipitate is a four- or five-step process.

#### **Step 1: Pretreatment**

Prior to metal precipitation, pretreatment processes sometimes are used to remove or manage substances that may interfere with hydroxide precipitation. For example, groundwater may need to be disinfected to destroy excess bacteria that could cause fouling inside the pipes and tanks of the treatment system. In other cases, precipitation aids such as ferrous sulfate and sodium hydrosulfite are added to condition the water and to help remove dissolved metals from solution. However, this tends to generate significant amounts of waste sludge that must be collected and managed. Calcium chloride and aluminum sulfate are used during a pretreatment step as conditioning agents when fluoride, phosphate, silicates, or emulsified oil needs to be removed from an effluent stream (wastewater).

#### **Step 2: Precipitation**

In precipitation metals dissolved in groundwater are made insoluble, usually as metal hydroxides. Adding alkali treatment chemicals to the water most frequently accomplishes this. Alkalis are soluble salts that are capable of neutralizing acid. They consist mainly of calcium, sodium, or potassium. The two alkalis that commonly are used for hydroxide precipitation are sodium hydroxide (also called caustic soda or just caustic) and calcium hydroxide or hydrated lime ( $\text{Ca}(\text{OH})_2$ , or more simply lime). Other typically used alkalis are magnesium hydroxide, calcium chloride, sodium carbonate, and sodium bicarbonate. Each alkali has advantages and disadvantages. For

example, of the two most common alkalis, hydrated lime is less expensive than caustic soda. Also, the metal hydroxide precipitants produced by using lime have much faster settling rates. Lime, however, takes longer to react than caustic soda and requires a more complicated feeder system. More importantly, lime generates a much higher amount of waste sludge.

The metal precipitation process begins by adding enough alkali material to raise the pH of the water to between 8.5 and 10.0. This is done in a tank called a neutralizer. Each metal hydroxide has a characteristic solubility that is dependent on pH. If the wastewater contains more than one metal, it becomes necessary to compromise among them in establishing a specific pH goal. Driving that compromise is the need to ensure treatment for the most environmentally damaging metal that may be present. Zinc, little more than a nuisance compound, is removed at a pH of 9, but the more dangerous cadmium requires a pH of 11. In this case, the higher pH would be the target level for the process.

The residence, or length of time the groundwater has contact with the alkali, depends upon the chemistry. Assuming good mixing, a minimum of 15 minutes residence is required if sodium hydroxide is used as the alkali. With lime, a minimum of 30 minutes is needed. The amount of metal that remains in solution after pH adjustment depends on the pH set point, the amount and types of metals in the groundwater, and the presence of any compounds that interfere with precipitation.

#### **Step 3: Flocculation**

The precipitated metal initially forms into a colloidal-particle material that has a soft, jellylike appearance. To remove the material from the water, nearly every metal treatment system uses chemical additives to encourage the precipitated metal colloids to join. In this process, called flocculation, chemicals are added so that floating colloids of precipitated metals develop into more solid, fast-settling particles that can be separated from the water. Flocculants commonly used are such inorganic compounds as alum and ferrous sulfate as well as a wide variety of commercially developed organic polyelectrolytes. These are water-soluble chemicals that adhere to the surface of the colloidal particles and discharge the electrical charges present on them to enable flocculation to occur. Organic polyelectrolytes are more efficient in promoting flocculation but are expensive and have to be tailored to the chemistry of the wastewater.

#### **Step 4: Clarification**

Removal of solids by gravity settling, called clarification, is the most typical way to separate insoluble

precipitated metals from treated groundwater before it is returned to the environment. Clarification is a fairly simple process that uses the difference in density between the flocculent-precipitated metals and water.

Clarifiers are circular tanks where treated groundwater is sent from the equalizer for the removal and eventual collection of the floating, precipitated metals. The water enters either the center or the side of the tank. The bottoms of some clarifiers are tilted toward the center of the tank, forming an inverted cone. In these types of tanks, sludge is usually collected in a hopper near the center of the tank base. Other clarifiers use mechanical sludge rakes and surface skimming to move sludge gently into collection sumps.

It is very important to remove most of the flocculent-precipitated metals, also called suspended solids, from the treated water. Suspended solids cloud the water, making it aesthetically unappealing, and may interfere with biological activities in the surface water where it is discharged. In addition, bacteria can attach to or use the suspended solids as hosts or growth media and increase the risk of disease transmission. Finally, the metal or metals removed from the groundwater can redissolve and contaminate the receiving stream. A well-designed and efficiently operated clarifier can treat the waste stream to remove all but 5–10 mcg/L of suspended solids.

### Step 5: Polishing

Clarification is the simplest part of the wastewater treatment process, but it also is the part that is most subject to problems. Regulatory agencies place strict limits on the amounts of suspended solids in discharged wastewater. Frequently, excess suspended solids in the treated water, caused by changes in wastewater characteristics or inefficient plant operation, make compliance with strict pollutant guidelines difficult. Therefore, many treatment facilities use a polishing filter to remove residual suspended solids that may escape the clarifier. Types of polishing filters include sand beds, mixed-media filters, and membrane filters.

Sand beds, also called granular media polishing filters, remove suspended solids from wastewater in the 5–50-mcg/L concentration range. These units typically contain graded sand or a mixture of inert particles such as garnet, pulverized coal, or silica. Similarly to the sand filters used in many swimming pools, suspended solids present in the wastewater are removed by straining. Periodically, the sand beds need to be “backwashed,” or flushed with air or water, to remove the collected solids.

Multimedia filters consist of two or more particle types that have both different grain size and differ-

ent densities. In a three-part multimedia filter, particles with the smallest grain size are also the densest, commonly garnet (density 4.5 g/cm<sup>3</sup>) at a particle size of 0.008–0.016 inch (0.2–0.4 mm). The midsize particles are 0.02 inch (0.5 mm) and an average density of 2.65 g/cm<sup>3</sup>, and the largest particles are 0.04 inch (1.0 mm) and the lightest (typically anthracite) with a density of 1.6 g/cm<sup>3</sup>. If thoroughly mixed and allowed to settle slowly, the multimedia bed grades itself according to the density of the material. The smallest particles will be on the bottom and the largest particles on top. When the wastewater flows from top to bottom, the bigger suspended solids are removed in the upper layers of the filter and the smaller suspended solids near the bottom. This filter also needs to be backwashed in a manner similar to that used for sand beds.

Membrane filtration is one of the most sophisticated and expensive polishing technologies and is most commonly used by metal plating and printed circuit board manufacturing companies as a pretreatment step prior to discharge of wastewater to a sanitary sewer system. Membranes are simply filters that separate, on a molecular level, the components of a mixture on the basis of their size. To do so, the wastewater or concentrate is passed, under pressure, across the semipermeable membrane, and those particles smaller than the pore spaces in the membrane pass through. The membranes can be made out of ceramics, special metal alloys, or even bundled carbon fibers.

Precipitation processes are effective and commonly used to clean metal-contaminated groundwater but have some limitations. Certain organic compounds such as ethylenediaminetetraacetic acid (EDTA) and nitrilotriacetate (NTA) can act as chelating agents, making it difficult to precipitate the metals unless additional treatment chemicals are added to the wastewater. This may significantly increase treatment costs and the amount of sludge generated by the process. The precipitation/clarification process cannot remove suspended solids below concentrations of approximately 5–10 mg/L unless polishing filtration is used. The suspended solids remaining in the wastewater contain metals that can limit the ability of the system to meet regulatory standards. The solubility of metals is dependent on pH. Therefore, a compromise must be made during system operation to ensure that the most environmentally damaging metals are removed from multimetal-contaminated wastewater. This compromise may also limit the overall ability of the system to achieve water quality standards and require multiple treatment steps. Finally, some metal hydroxide sludge may be so concentrated

that it exhibits characteristics of hazardous waste. Indeed, the U.S. Environmental Protection Agency (EPA) has classified sludge from the treatment of electroplating wastewater as hazardous. Such sludge must be specially managed, handled, transported, and recycled or disposed of, at greatly increased operating costs.

### GRANULATED ACTIVATED CARBON (GAC)

Carbon is an essential element for the environmental scientist, not just because it serves as the basis for all life on the planet, but because it has the rare ability to attract and hold, or adsorb, a wide variety of common environmental contaminants. Adsorption is the physical attraction and adherence of gas or liquid (vapor) molecules onto the surface of a solid. Safe, inert, easy to handle, and relatively inexpensive, activated carbon is widely recognized as the most effective way to treat groundwater containing organic solvents as well as certain metals. Activated carbon is produced or manufactured in three steps.

The first step, called carbonization, is to select the raw material, which can be almost any carbonaceous substance, coal, sawdust, or any plant matter. This material is then slowly heated in the absence of air and becomes a charcoal-like highly porous adsorbent material. The choice of the raw material influences the pore structure, particle size, void space, and sur-

face area of the carbon that is eventually produced. The next step, called dehydration, is usually accomplished during carbonization, as the raw material is heated. Once most of the water has been removed from the raw material, it is ready for activation. This process is intended to expand or open up the pore spaces of the raw material and greatly increase its ability to adsorb. There are two types of activation processes, chemical activation and steam activation.

In chemical activation, which is usually used with peat and wood-based raw materials, the carbon is impregnated with a strong dehydrating agent, typically phosphoric acid ( $P_2O_5$ ) or zinc chloride ( $ZnCl_2$ ), and heated to 570–930°F (500–800°C). The resultant “activated” carbon is washed, dried, and ground to powder. Chemical activation produces carbon with a very open pore structure, ideal for the adsorption of large molecules. Steam activation, generally used with coal and coconut shells, occurs when the carbon source is heated to 1,500–2,000°F (800–1,100°C) in the presence of steam. Carbon produced by steam activation exhibits a fine pore structure, very useful for the adsorption of contaminants from both liquids and vapors. The resultant activated carbon is graded, screened, and dedusted. When used for treatment of contaminated groundwater, activated carbon, also called activated charcoal or granular activated carbon (GAC), can be purchased in block, granulated, or powdered form.

Once it is activated, the carbon’s internal surface area dramatically increases to 10,200–12,400 square feet (950–1,150 m<sup>2</sup>) per gram. This means that one pound (0.45 kg) of activated carbon has a surface area of 60–150 acres (24–60 ha). This enormous surface area per unit of GAC is where the adsorbed gases and vapors are held and the adsorption of carbon takes place. If a molecule of organic solvent (trichloroethylene [TCE], for example) has contact with the surface of an activated carbon particle, the unbalanced electrical forces on and within the carbon particle cause the TCE molecule to move down into the smaller pores of the carbon particle. It stops when either the electrical forces become balanced or it is physically blocked.

Treatment systems using GAC are relatively simple to design, can be quickly installed, and are easy to operate. Contaminated groundwater is pumped to a settling tank or through a particulate filter to remove sand, grit, or other large particles that may clog or foul the GAC bed. Once filtered, the wastewater is directed to a carbon bed, usually a cylindrical tank filled with carbon. The contaminated groundwater flows down and through the tank, and the carbon removes the TCE and other contaminants. Treated water is tested to make sure it meets

**Diagram of carbon treatment system for contaminated groundwater. Wastewater enters the system from the left and treated water exits from the right.**

permit or discharge concentrations for the contamination and is released to either a sanitary sewer or a surface water body.

Despite GAC's enormous surface area, eventually it becomes saturated with adsorbed molecules. When this happens, contaminant breakthrough occurs, and the contaminants in the water leaving the carbon tank no longer meet required discharge quality. The GAC is considered "spent" and must be removed for regeneration. The spent GAC is physically transported to a separate facility, where it is heated to 1,500–1,700°F (820–930°C). This process clears about 90–95 percent of the pores. Off-gases from the regeneration process are collected and treated and the carbon is returned to service. How often any given GAC system can operate between regeneration events depends on the strength of the contaminated water and the strictness of the limits for the discharged water.

GAC is not the most efficient way to treat wastewater with high amounts of suspended solids (>50 mg/L) and oil and grease (>10 mg/L) because of fouling problems. Multiple contaminants also can affect system performance, as some contaminants are adsorbed and others not. Finally, system costs can be high compared to those of other technologies if GAC is used as the primary treatment mechanism. Regeneration of carbon is expensive, and eventually the carbon requires proper disposal. GAC is used most commonly as a polishing step after treatment by a bioreactor or air stripping to remove the final residual concentrations of contaminants before treated groundwater is discharged.

Although GAC is the most common adsorbent, there are other natural and synthetic adsorbents used in groundwater treatment systems. These include the following:

#### **Activated Alumina (AA)**

A filter is made by processing aluminum ore to make it porous and therefore highly adsorptive. AA removes fluoride, arsenic, and selenium, but it requires periodic flushing with a special chemical such as alum or acid in order to remain effective.

#### **Forage Sponge**

Forage sponge is a cellulose sponge that is coated with an amine polymer that absorbs certain types of dissolved heavy metals. The polymer can be designed to attract heavy metals in both cationic (positively charged) and anionic (negatively charged) states.

#### **Lignin Adsorption/Sorptive Clay**

These clays are used to treat wastewater contaminated with organics, inorganic compounds, and

heavy metals. The contamination is attracted and held on the adsorptive surface of the clay.

#### **Synthetic Resins**

More expensive than GAC, synthetic resins can be designed to be more selective and adsorb better. They are regenerated by flushing with acids, bases, or organic solvents, but not thermal methods. For this reason, resins are better suited for explosives. They also are less sensitive to dissolved solids and tend to be more resistant to abrasion than activated carbon.

#### **ION EXCHANGE**

"Hard" water is more of a household nuisance than an environmental concern, but the equipment available to deal with it illustrates ion exchange groundwater treatment technology. As water flows through the subsurface, it dissolves certain minerals that are naturally present in the soil, especially those rich in calcium and magnesium, but also some sodium, potassium, and nitrate. Water containing high concentrations of these elements and compounds, particularly calcium and magnesium, is called hard water. Ordinary soap, which is made up mostly of fatty acids, forms an insoluble salt when mixed with calcium or magnesium. Washing with soap in hard water reduces its ability to form lather, and it produces a dingy precipitate that gives clothing a gray hue. The higher the levels of calcium and magnesium, the less lather can be made. Hard water is defined as containing more than 250 parts per million (ppm) of total calcium and magnesium ions. Hardness can also be expressed in grains of calcium per gallon, or gpg, where 17.1 ppm equals one grain of hardness.

If the calcium and magnesium dissolved in the groundwater enter a household plumbing system, they precipitate on the insides of the pipes and water heaters, forming a scale. This scale slowly builds up and eventually constricts the flow of water through the system. It also prematurely ages hot water heaters and furnaces. Water with greater than 150 ppm is hard enough to require treatment to remove the calcium or magnesium. If hardness exceeds 250–300 ppm, treatment becomes a necessity. At levels of 100–250 ppm, water treatment is done for aesthetic purposes.

Water treatment reduces staining of fixtures and surfaces, as well as making hair and skin feel softer. In an industrial steam boiler, treatment of hard water is a necessity as scale quickly interferes with water circulation and heat transfer and can catastrophically destroy the boiler. The higher the operating pressure of the boiler the more critical the

**Diagram of the basic components of a soil washing system. Contaminated soil is loaded into the scrubbing unit with water and detergent. In some cases, the system cleans the soil completely, but in others, the soil is still too contaminated to be released. The wastewater must be treated and can be either released or recirculated back into scrubbing unit.**

removal of calcium, magnesium, and other dissolved minerals from the water becomes. Large utility boilers operating at 3,000 pounds per square inch of gas (psig) or more may use distilled water to minimize scale buildup.

One of the most effective ways to treat hard water is to use a water “softener” to remove the calcium and magnesium. This is done through a reversible chemical reaction called ion exchange or ion substitution. An ion is an atom or molecule that has lost or gained an electron and thus acquired an electrical charge, either positive or negative. If dissolved in water, an ion can be easily exchanged for a similarly charged ion that is attached to an immobile solid particle.

Water is electrically neutral because the dissolved ions travel in pairs, one positively charged, called a cation, and one negatively charged, called an anion. Calcium cation ( $\text{Ca}^+$ ) present in the water is matched up with a carbonate anion ( $\text{CO}_3^-$ ) to form calcium carbonate, or the mineral calcite. Similarly, positively charged magnesium cations are connected to negatively charged carbonate anions to form magnesite ( $\text{MgCO}_3$ ). Sodium ( $\text{Na}^+$ ) is a cation that is associated with the anion chloride to form sodium chloride, or common table salt. The important characteristic of sodium is that it is “soft,” in that it does not interact with soap nor clog pipes or furnaces. This makes it ideal for use as a water softener.

To soften water by substituting sodium ions for calcium or magnesium ions, thousands of tiny, negatively charged beads are made from hardened plastic resin. Depending upon the type of material used to

make the resin, these beads can be designed with either a positive or a negative electrical charges. Next, beads are coated with a layer of sodium chloride, or salt. The negative charge on the beads will tend to attract and hold positively charged sodium ions. The negatively charged resin beads coated with positively charged sodium ions are placed in a cylindrical tank. Hard water pumped into the top of the tank flows down into the beads. The positively charged calcium and magnesium ions in the water are strongly attracted to the negatively charged, sodium coated beads. As the “hard” ions attach to the bead, they displace the “soft” sodium ions. The sodium is exchanged for the calcium and magnesium, and, at the end of this exchange or substitution process, “soft” water flows from the bottom of the tank.

Some types of water softeners use a naturally occurring claylike material called zeolite, a group of porous minerals containing sodium, aluminum, and silica. Their atomic structure is arranged so that water can easily pass through it. When this happens, the sodium ions can be exchanged for other ions dissolved in water, such as calcium and magnesium. Zeolites are somewhat less expensive to use than resin beads, but not as efficient at removing ions from water.

Eventually, the resin beads or zeolite in the tank of the water softener becomes saturated with calcium and/or magnesium and need to be renewed. The exchange or substitution process is reversible, so a strong salt solution pushed through the tank holding the resin or zeolite can flush out hard water.

The softener can be returned to service, with a fresh coating of sodium ions present on the resin beads or coating the zeolite crystals.

The ability of some materials to exchange one ion for another is a useful property in the remediation of contaminated groundwater. Environmental scientists and engineers use ion exchange or ion substitution to treat groundwater that has been contaminated by such heavy metals as copper, chromium, and lead. In this type of application, the contaminated water is run through a series of resin beds so that dissolved minerals are removed. However, to ensure effective treatment of contaminated groundwater, both the cation and the anion need to be removed or exchanged, and, since resins cannot be both positively and negatively charged simultaneously, two different types of resins are required. The most direct method is to design a system that places a positively charged cation exchange resin in one tank and a negatively charged anion exchange resin in another. Contaminated groundwater flows first through the tank holding cation resin and then the tank with anion resin. The treated water then is discharged or recirculated.

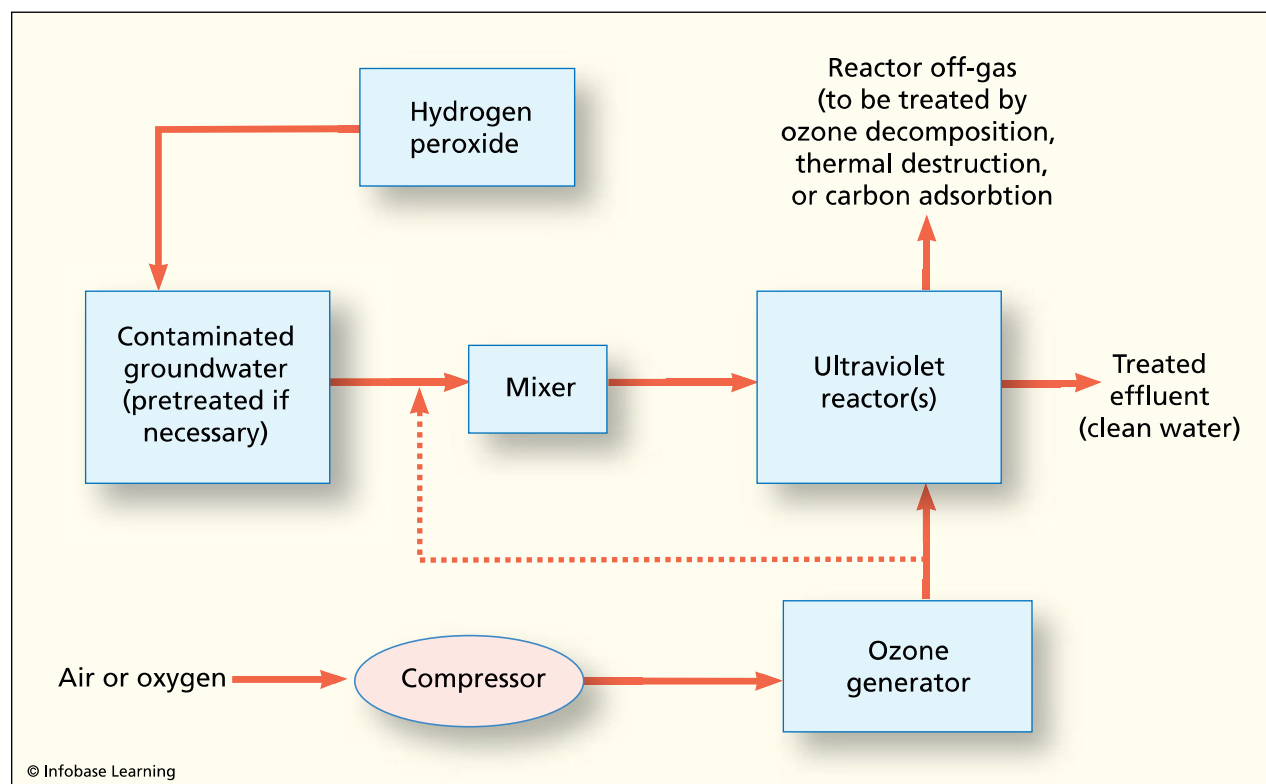

In the cation tank, specially designed high-molecular-weight polyelectrolytic resins exchange hydrogen ions ( $H^+$ ) for positively charged metallic ions

such as nickel, copper, or sodium. Treated water then moves into the anion tank, where similar resins exchange hydroxyl ions ( $OH^-$ ) for the negatively charged nonmetallic part of the mineral such as sulfates, carbonates, and chlorides. The exchange process adds the same quantity of  $H^+$  and  $OH^-$  ions to the wastewater, so the water that is discharged is pH neutral and relatively pure. Just as water softeners do, cation exchange resins need to be periodically renewed, by washing them with hydrochloric (HCl) or sulfuric ( $H_2SO_4$ ) acid.

As with carbon adsorption, ion exchange is seldom used as the primary treatment process. More commonly deployed as a polishing step, ion exchange systems can be difficult to design and expensive to operate for systems with high-volume influent flows.

### UV/OXIDATION

Ultraviolet oxidation (UV/O) is a process that eliminates contaminants from groundwater. Air stripping, GAC, precipitation, and the other technologies transfer the contaminant mass from water to another medium for easier handling and disposal. UV/O uses a two-tiered procedure to destroy a wide variety of contaminants using ultraviolet radiation in combination with ozone gas or hydrogen peroxide.

Schematic diagram showing the flow path in an ultraviolet and ozone oxidation groundwater treatment system

First, an oxidizing agent, typically ozone ( $O_3$ ) or hydrogen peroxide ( $H_2O_2$ ), is added to the wastewater. These chemicals react with contaminants in the water and break apart the chemical bonds holding them together. Whether to use ozone or hydrogen peroxide as the oxidizing agent is dependent upon what type of contaminant is present in the wastewater. Ozone works well with many types of organic molecules such as TCE, tetrachloroethylene (PCE), and vinyl chloride, as well as aromatic compounds such as toluene, benzene, xylene, and phenol. Chemicals that react well with hydrogen peroxide include nitriles, aldehydes, alcohols, amines, metals, alkylboranes, azocompounds, cyanides, phenols, sulfides, and chromium. In certain systems, both ozone and hydrogen peroxide are added as oxidizing agents.

Ozone naturally decomposes in water to form hydroxyl radicals ( $OH^\cdot$ ) and hydrogen peroxide; if an iron catalyst is added, it will do the same. These hydroxyl radicals break down contaminants at a much faster rate than just the ozone or hydrogen peroxide alone. Therefore, one way to speed up the treatment process is to increase the number and effectiveness of hydroxyl radicals that form from the addition of ozone or hydrogen peroxide to the contaminated groundwater. This is when the use of ultraviolet radiation becomes important. Once saturated with ozone, hydrogen peroxide, or both, wastewater is pumped to a tank, where it is exposed to a high-intensity, ultraviolet radiation source.

Ultraviolet light is also called ultraviolet radiation, or UVR, and is a form of electromagnetic radiation similar to visible light, radar, and radio signals. Electromagnetic radiation is transmitted in waves. UVR has a wavelength shorter than that of visible light but has a much higher frequency, or energy level. Within the electromagnetic spectrum, UVR is between the blue end of the visible range and low-energy X-rays. UVR is separated into three bands based on increasing energy levels and general biological effects:

### **UV-A**

With a wavelength of 315–400 nanometers (nm) and commonly called black light, UV-A is the least energetic UV band and less effective than UV-B in causing sunburn (erythema) and tanning. UV-A penetrates deeper in the skin because of its longer wavelength and plays a role in the premature aging of skin and increased incidence of skin cancer and eye cataracts. “Black lights” are UV-A lamps used for nondestructive testing and, insect control and in the entertainment industry.

### **UV-B**

With a wavelength of 280–315 nm, erythema UV is the most effective UV band for tanning and sunburn (erythema). It can affect the immune system. Therapeutic UVR lamps, used in physiotherapy and dermatology for the treatment of psoriasis and other skin conditions, can emit either UV-A or UV-B.

### **UV-C**

With a wavelength of 100–280 nm, germicidal UV can damage deoxyribonucleic acid (DNA) and other molecules and is often used as an antibacterial agent. The atmospheric ozone layer rapidly attenuates UV-C in air, and UV-C is not found in ground-level solar radiation. Exposure to UV-C, however, can take place close to sources such as welding arcs. Germicidal lamps, used for sterilization in hospitals, are strong emitters of UV-B and UV-C radiation.

UV-B and UV-C are powerful enough to break apart the molecular and chemical bonds present in many common groundwater contaminants. They can degrade polychlorinated biphenyls (PCBs), dioxins, polycyclic aromatic hydrocarbons (PAHs), and BTEX (benzene, toluene, ethylbenzene, xylene), but the real value of UV-B/C is that it enhances chemical oxidation, probably by increasing the number of hydroxyl radicals that form if ozone or hydrogen peroxide is added to wastewater. It is likely that the energy added to the water from the UV-B/C radiation speeds up the formation of hydroxyl radicals, and it is these radicals that attack and break apart the complex organic molecules that make up the contaminants. With a full-scale UV/ozone/peroxide system, groundwater contaminated with halogenated solvents, phenol, pentachlorophenol, pesticides, PCBs, explosives, BTEX, methyl tert-butyl ether (MTBE), and many other organic compounds can be treated effectively.

A typical UV/O system consists of an air compressor with an ozone generator and a hydrogen peroxide injection system. Passing an electrical current through a column of water generates the ozone. The water molecules are broken apart into hydrogen and oxygen atoms. The hydrogen molecules then are separated from the gas/water mixture, and the oxygen is combined to form ozone ( $O_3$ ) and oxygen ( $O_2$ ). The ozone is injected as a gas into the contaminated groundwater. Hydrogen peroxide is added as a liquid and mixed with it. The groundwater, now saturated with ozone and hydrogen peroxide, flows past a strong source of UV light. UV radiation is generated by low-pressure mercury vapor lamps that produce ultraviolet rays from an electrical discharge through low-pressure inert gases and mercury vapor within

a quartz tube. Approximately 95 percent of the UV rays from this type of lamp are at a wavelength of 254 nm (UV-C). The quartz tube prevents the water from having contact with the lamp but is transparent to UV light.

As with any remedial system, UV/O has limitations. A major factor in determining how well the UV/O system will function is the turbidity of the water. The cloudier the water, the more difficult it is to transmit the UV radiation through it. The water should be relatively free of heavy metals and insoluble oil or grease, as they tend to foul the UV lights. From an economic standpoint, these systems require large amounts of energy and can be fairly expensive to operate and maintain compared to other technologies. Finally, handling and storage of hydrogen peroxide, a very reactive chemical, require special safety precautions. Ozone is an air pollutant, and monitoring must be carried out so that ozone levels do not exceed regulatory limits.

There are several advantages to using a combined ultraviolet, ozone, and hydrogen peroxide process. UV/O is destructive, with contaminant end products of carbon dioxide, water, and inert salts. These residuals do not require further treatment. Also, a much wider variety of contaminants and concentrations can be treated with these types of systems.

## SEPARATION

Separation technologies detach or disconnect contaminants from groundwater or the suspended material that contains them. These technologies work on physical differences such as particle size, density, or vapor pressure between the contaminant and groundwater to segregate and remove them. Separation processes are some of the technologically simplest ways to address groundwater contamination.

### Coalescing Oil-Water Separators

These are passive, physical separation systems designed for the removal of oils, fuels, and hydraulic fluids from water. Oil-water separators use the difference in specific gravity between lighter oil and heavier water. Oil separates from a fluid at a rate explained by Stokes' law, which is a formula that predicts how fast an oil droplet will rise or settle through water on the basis of the density and size of the oil droplet and the distance the droplet must travel. In an oil-water separator, the water-oil mixture enters the separator and is dispersed horizontally by diffusion. Dense solids settle out in this part of the separator and light particles of oil rise to the surface.

The mixture then flows to a coalescing chamber, where it strikes a series of stacked plates. The oil combines into larger droplets and rises upward, forming a coherent layer. As the oil rises, remaining solids also strike the plates and slide down into a hopper for collection and disposal. The oil accumulates in the upper part of the separator, and when a sufficient volume has gathered, it is removed by a pump. Clean water is discharged from the bottom of the separator.

Oil-water separators typically are installed as pretreatment devices, often combined with a settling chamber. They are used to collect storm-water runoff from parking lots and gas stations before discharging the water component to the municipal sewer system for further treatment. Oil-water separators do not address chemical contaminants dissolved in groundwater, but they are effective in removing oils, greases, and other floating layers with physical differences from the water.

### Distillation

This process achieves contaminant separation by vaporization and condensation. It is based on the volatility of the material dissolved in the wastewater. In a single-stage distillation system, heat is applied to a liquid mixture in a still. This causes part of the liquid to vaporize. The vapors are collected and cooled, subsequently condensing and forming a liquid called distillate. The distillate is actually a concentrate of the higher-volatility components of the contaminants that evaporated out of the wastewater. The material remaining in the still, called the bottoms, contains components that are less volatile. In most commercial distillation operations, multiple, or repeat, staging is used to obtain better separation of organic components than is possible in a single evaporation and condensation stage.

Distillation is a common process for the purification of seawater, with salts and minerals being concentrated. Certain organic compounds and radionuclides, however, can travel with the water once it is evaporated, and GAC filters often are used in connection with distillation to make sure these unwanted contaminants are removed before the distilled water is discharged. Distillation produces very pure water and is effective in removing nitrates, chloride, and other salts that carbon filtration cannot. It also destroys bacteria and parasites that may be present in the water. Distillation, however, takes time to purify the water and uses relatively high amounts of energy. Maintenance requirements for these types of systems also are extensive.

### Freeze Crystallization

This process removes contaminants from solution as frozen crystals. Groundwater slowly is frozen and ice crystals form on its surface. The contaminants are concentrated in the unfrozen remaining solution, called mother liquor. The ice crystals then are collected, washed, and melted to form relatively pure water. Mother liquor and related precipitated solids are now more easily treated because of their higher concentrations.

Freeze crystallization is used at many winter resorts to treat the higher volumes of sanitary wastewater that are generated during ski or winter holiday seasons. In Ottawa, Canada, freeze crystallization is used during winter months to help manage that city's sanitary wastewater. In freezing weather, and after solids separation, wastewater is pumped at high pressure to atomizing nozzles, where compressed air sprays fine droplets into the atmosphere. Spraying cause gases such as carbon dioxide to be stripped away, raising pH values. Higher pH encourages a variety of beneficial chemical reactions within the meltwater. As the droplets freeze, water is transformed into hexagonal crystalline structures that reject incorporation of impurities. As a result, contaminants are physically separated from the water but remain trapped within the center of the frozen droplets.

The ice particles accumulate in the snowpack throughout the winter, degrading as they age. Nutrients, such as phosphorus, precipitate in insoluble form and do not redissolve into the melting snow. Other soluble salts also precipitate and organics collect on the precipitating salts. As ice crystals in the snowpack age, they fuse together, forming larger crystals called corn or sugar snow. This allows some of the entrapped contaminants to escape as gases, and others, as precipitated solids, move to the bottom of the snowpack. Depending on soil characteristics, meltwater from the snowpack either infiltrates or can be collected for later treatment or discharge. The soil beneath the snowpack generally remains frozen during winter, so infiltration of meltwater begins early in the spring. The nutrient residues left after meltwater dissipates provide a weak fertilizer for on-site vegetation, such as grasses.

### Filtration

Filtration works by forcing groundwater through a porous medium that mechanically separates or traps the particles suspended in it. Particles whose sizes are smaller than the openings of the medium or semipermeable membrane are allowed to pass flow through the membrane. Depending upon the size of the trapped particles, filtration can be classified

as microfiltration (pore size greater than 50 nm) or ultrafiltration (pore size 2–50 nm). A number of commercial filtration systems are available, most based on the use of specialty fabrics or composites. Limiting the widespread use of filtration as a remedial solution are relatively high maintenance costs associated with filter change out and the need for subsequent treatment and disposal of collected solids.

### Membrane Pervaporation

Membrane pervaporation is a process that uses permeable membranes preferentially to adsorb volatile organic compounds (VOCs) from contaminated water. A heat exchanger first raises the temperature of contaminated water. From there, it is pumped through a pervaporation unit. This contains semipermeable membranes made up of a nonporous material shaped into capillary fibers that attracts organic and oily substances and repels water. Nitrile, butadiene rubber, and styrene butadiene rubber are types of materials used. A vacuum is applied to one side of the unit and VOCs diffuse through the membrane. Treated water flows out of the pervaporation unit and the VOCs in vapor form are captured by a condenser and collected for separate disposal. The condensed VOCs are only a fraction of the initial contaminated water volume and, therefore, disposal costs are greatly reduced.

Over time, as material flows through the membrane, a swelling effect makes it more permeable and less selective. Eventually, the membrane is exhausted and must be replaced or renewed. Continuous pervaporation consumes relatively low amounts of energy and operates most efficiently at low contaminant concentrations. It is also better suited for high wastewater flow rates.

### Reverse Osmosis

There are two mechanisms by which molecules move through a membrane, active and passive transport. Active transport requires energy to transport molecules through the membrane and is commonly seen in living organisms as water moving in or out of a cell. Passive transport occurs spontaneously and is governed by the principle of diffusion.

Diffusion is the net movement of molecules from an area of high concentration to an area of low concentration. Diffusion is dependent on temperature and continues until the molecules are randomly distributed throughout the system. Osmosis is a type of diffusion. If two water or other solvent volumes are separated by a semipermeable membrane such as a cell wall or piece of porous rubber, water will flow from the side of low solute concentration to the side of high solute concentration. If a volume

of salt water is separated from a volume of freshwater by a semipermeable membrane, for example, the freshwater will move, by diffusion, through the membrane toward the salt water. This diffusion, or osmosis, continues until the concentration of salt in the water is the same on both sides of the membrane. The final pressure difference between the two sides of the membrane is equal to the osmotic pressure of the solution.

To reverse the flow of water or solvent, pressure greater than the osmotic pressure is applied. If this occurs, the solvent (water) separates from the solute (the groundwater contaminant) and moves through the semipermeable membrane. This is reverse osmosis, sometimes called hyperfiltration, because the semipermeable membrane essentially acts as a filter to retain the ions and particles while allowing water to flow through. Purified water passing through the membrane is called permeate, whereas liquid containing the retained metals is the concentrate. Metal or salt products can be removed from concentrate by evaporation or precipitation. The three most commonly used membrane materials are cellulose acetate (processed wood pulp); aromatic polyamide, a film-forming polymer such as Kevlar; and membranes made of thin-film, solute-rejecting composites.

Membranes can degrade or foul, so pretreatment of wastewater is often necessary to remove suspended solids or solids formed by precipitation of iron or manganese. Very high or low pH can also result in membrane degradation. The reverse osmosis process is not ion selective, so it captures all ions, not just the unwanted ones. The process also can generate significant amounts of residues that require further treatment or disposal. Reverse osmosis, however, removes most contaminants and is a well-known remediation technique for groundwater. It is used for the removal of dissolved solids, especially organics and nitrates, from water.

### SPRINKLER IRRIGATION

One of the simplest remedial technologies available for treating groundwater contaminated with VOCs is to spray it in the air through a sprinkler irrigation system. The sudden increase in surface area caused by spraying encourages the VOCs to move from the dissolved aqueous phase to the vapor phase. The VOCs vaporize and are released directly into the atmosphere.

This type of remedial approach is severely limited in its application. It is not appropriate for groundwater containing nonvolatile compounds such as metals or radionuclides. Regulatory approval for it is

difficult to obtain, unless the VOC concentrations are very low, because of the uncontrolled release of contaminants to the atmosphere. Significant land area is needed to install and operate the system, and runoff of accumulated spray may result in erosion, nuisance ponding, or surface water quality issues. The effectiveness of the system is dependent upon higher temperatures, and the system loses efficiency during winter months. Finally, suspended solids or solids formed by precipitation of iron or manganese can plug spray nozzles, requiring frequent maintenance or even pretreatment.

### CONSTRUCTED WETLANDS

Since the early 1700s, wetlands such as swamps, bogs, marshes, and sloughs were regarded by most as wasted and unproductive property. Long recognized as a breeding ground for “night vapors,” “bad air,” insects, and other pests, wetlands provoked public and scientific disdain that peaked in the late 1800s, when a young doctor from Johns Hopkins Medical School let a mosquito in a yellow fever ward bite his hand. Twelve days later, this doctor died, but he proved that mosquitoes, not people, transmitted yellow fever. With this finding, there was a rush to fill wetlands, legitimized by public health concerns and fueled by money realized as part of the redevelopment process. Large parts of New York City, New Orleans, San Francisco, and Philadelphia are built on “recovered” wetlands. By the mid-1950s, more than half of the wetlands in the United States had been drained, filled, farmed, or paved.

By the 1960s and 1970s, attitudes began to change as the environmental movement took hold and biologists and engineers began to realize that wetlands play a crucial role in ecosystem habitat, flood management, and pollution control. A turning point in the understanding and appreciation of wetlands occurred in 1994, when new federal legislation greatly restricted filling or destruction of wetlands and required that natural wetlands not already drained be preserved for wildlife and as part of an existing hydrologic system.

The use of wetlands as a groundwater treatment mechanism is a fairly new and still somewhat innovative concept. The technology relies on the organic materials, microbial fauna, and algae naturally present in wetland systems to attack and breakdown contamination. Water with organic contaminants such as VOCs or S(semi)VOCs, low pH from acid mine drainage, or containing metals flows through the aerobic and anaerobic zones of the wetland. Ion exchange, adsorption, absorption, and precipitation through geochemical and

microbial oxidation and reduction remove organic contaminants and heavy metals. Sorption of metals also takes place as water has contact with humic and other organic substances in wetland sediment. Oxidation and reduction occur in the aerobic and anaerobic zones, respectively, and transform or degrade organics and precipitate metals as hydroxides and sulfides. Precipitated and adsorbed metals settle in quiescent ponds or are filtered out as the water percolates through the sediment. Wetlands can remove fecal coliform, total petroleum hydrocarbons, and such metals as lead, chromium, and zinc. Constructed wetlands are used in municipal sanitary wastewater treatment for managing organic matter, excess nitrogen and phosphorus, and suspended solids.

Constructed wetlands are of two basic types, free water surface and vegetated submerged bed. Both types can include liners to reduce the likelihood of contaminants' reentering the groundwater. Free water surface (FWS) wetlands are those that look most natural. They include open-water areas with changing water depths and emergent or visible vegetation. Distinguishing FWS wetlands from naturally occurring wetlands are inlet devices designed to control wastewater distribution into the system, soil or earthen dikes that define the treatment cells, and carefully organized combinations of open water areas and vegetation that optimize treatment. An outlet structure completes the system and is used to manage water levels within the wetland as well as discharge.

Vegetated submerged bed (VSB) wetlands contain most of the same features as FWS systems including inlet and outlet structures and treatment cells defined by earthen dikes or berms, but they are much simpler in design. VSB wetlands are essentially layers of gravel that have been planted with various types of wetland vegetation. In this system, the water level is maintained below the top of the gravel layer and areas of free-standing water are not visible. Water treatment takes place within the gravel beds.

Several factors limit the applicability and effectiveness of constructed wetlands as a remedial technology. Depending upon the types of contamination and their concentrations, a fairly large (tens of acres) land area may be needed to develop an effective treatment approach. And the long-term effectiveness of constructed wetland treatment is not well known. Contaminant removal rates may decrease over time and require the installation of a new technology or an expansion of the wetland. Local climate or even seasonal weather patterns also play a pivotal role in the success of this technology. Cold air temperatures can slow biological processes and result in inconsis-

tent contaminant degradation rates. Excess precipitation can flood a system, and below-normal rainfall amounts (drought) can damage or destroy needed vegetation.

## **Exxon Valdez oil spill Prince William Sound, Alaska March 24, 1989 Water Pollution**

ExxonMobil is one of the world's largest companies and has been for several years. It also is the biggest oil producing and refining business on the planet, with the most proven reserves. John D. Rockefeller founded the Standard Oil Trust, or simply Standard Oil Company, in the early 1880s, to process and distribute industrial greases, lubricants, and kerosene. The company moved into petroleum and grew into a giant based on what its critics feel were questionable business tactics. In 1911, after long litigation, the U.S. Supreme Court ordered that Standard Oil be broken up into separate, independently operated companies. Eventually 34 were established and two would become the predecessor companies of Exxon and Mobil, Standard Oil of New Jersey (later Esso) and Standard Oil of New York, or Socony.

Over the next 60 years, both companies developed as major worldwide suppliers and refiners of petroleum, industrial chemicals, and related products. Exxon was the largest American oil company for most of this time. To prosper in the business and regulatory climate of the 1980s and 1990s, their emphasis shifted to the import and marketing of oil rather than exploration and discovery. In 1998, Exxon and Mobil agreed to merge and become ExxonMobil Corporation.

### BACKGROUND

It came as no surprise that, in the early 1980s, Exxon commissioned the construction of the largest ship ever built on the West Coast of the United States to date. At 987 feet (300 m) long and 166 feet (50 m) wide, the *Exxon Valdez* was built to carry 1.5 million barrels (238.5 million L) of oil from terminals in Valdez, Alaska, to refineries 800 miles (1,288 km) away in the continental United States. With a crew of 21, and powered by an eight-cylinder reversible, slow-stroke marine diesel engine, the *Exxon Valdez* could cruise at 21 knots (about 19 miles per hour, or 30.6 km/h) fully loaded. The *Exxon Valdez* was built to meet all international and U.S. safety standards. It had a unwelded hull, which is considered much stronger than a riveted hull, and the 10 cargo tanks, four ballast tanks, and two “slop” tanks were designed to provide maximal stability and cargo management flexibility in the event of damage. The *Exxon Valdez* also had incorporated one of the major safety improvements required of all new tankers being constructed at the time, a double bottom.

As the name implies, a double-bottom ship is one that has two watertight layers installed along the part of the hull in contact with water. The outermost steel skin is separated from the inner one by several feet, and, in the event of a breach of the outer hull, the inner hull prevents seawater from entering the vessel, or the vessel’s cargo from spilling into the sea. The annular space (the area between the hulls) is sometimes used to store ballast water and operating fuel. Double bottoms have been required on passenger ships for more than 30 years because of their higher safety rating.

The *Exxon Valdez*’s keel was laid on July 29, 1985, and she was delivered, after three months of sea trials, on December 6, 1986. The ship performed satisfactorily for more than three years, regularly making the journey up the West Coast of North America to the port of Valdez in Alaska. There it would transport oil from the Alaskan oil fields to refineries along the West Coast. Economically significant quantities of oil had been suspected to be pres-

Oil-absorbent rags used to wipe crude oil, spilled from the *Exxon Valdez*, off rocks on the beach of Naked Island, Prince William Sound, Alaska, April 7, 1989

ent in Alaska’s North Slope, but it was not until the late 1960s that oil prices had risen to high enough levels for Atlantic Richfield Company (ARCO) and Humble Oil (Exxon) to attempt the very expensive exploration studies needed in this harsh climate to confirm that a major oil field existed at Prudhoe Bay, near the Arctic Ocean. Both companies, joined by several others, formed a consortium that would become the Alyeska Pipeline Service Company. They proposed an 800-mile- (1,288-km-) long pipeline to convey the oil from Prudhoe Bay, near the Arctic Ocean, to the port of Valdez (population 4,000), where it could be loaded onto tanker ships for delivery to refineries in the United States. Valdez was chosen as the terminus of the Trans Alaska Pipeline System (TAPS) because it was an “ice-free” harbor. That is, the water did not routinely freeze during the long and very cold Alaskan winter, and, therefore, oil loading and shipping operations could take place year round.

When proposed in 1970, TAPS was an \$8-billion effort and one of the largest privately financed construction projects ever attempted. ExxonMobil has a 20 percent interest in the pipeline, along with such other oil companies as BP, ConocoPhillips, and Unocal. Environmental concerns slowed federal and state approval of the project, but they were eventually granted primarily because of the concern induced by the OPEC (Organization of Petroleum Exporting Countries) oil embargo of 1973. Pipeline construction began in March 1975 and was completed in May 1977. Oil from the Prudhoe Bay fields began to flow into terminals in Valdez on July 28, 1977, and the first fully loaded oil tanker, the *Arco Juneau*, sailed out of Valdez harbor toward California on August 1, 1977. Today, 70 tanker vessels sail into and out of Valdez every day, taking their important and very valuable cargo to the mainland United States.

### THE ACCIDENT AND OIL SPILL

The *Exxon Valdez* arrived at the port of Valdez on March 23, 1989, captained by Joseph Hazelwood, a very qualified and experienced skipper who had been sailing for Exxon for almost 20 years. Only three years old, the *Exxon Valdez* was the newest and most modern ship in the Exxon fleet, and it was quickly loaded almost to capacity with 1.3 million barrels (206.7 million L) of crude oil. By 9:00 p.m., it was ready to depart, and Hazelwood ordered the ship under way. Sailing southward, the *Exxon Valdez*, under the guidance of the harbor pilot, made its way safely through Valdez Narrow, the very tight (only 1,700-yard- [1.6-km-] wide) entrance to the harbor, and out into the somewhat more open waters of Prince William Sound.

Prince William Sound is an extension of the Gulf of Alaska. Lying east of the Kenai Peninsula, it is an open expanse of water some 100 miles (160.9 km) wide bordered on the east, north, and west by the Chugach Mountains. Glaciers have taken millions of years to carve out the approximately 3,000 miles (4,828 km) of shoreline surrounding the sound, and it is dotted with small islands, submerged ledges or reefs, and drowned river valleys (fjords) that form natural breakwaters and shelters from the winds and ice that originate from the Columbia Glacier along its northwestern side. These drowned valleys, reefs, and islands also form an important habitat for numerous types of seabirds, marine life, and commercial fisheries. Long recognized as a place of

pristine beauty and special ecological significance, the majority of the land surrounding Prince William Sound has been designated as national forest since 1907. In fact, Chugach National Forest is the second largest national forest in the United States, and, in 1974, Congress passed the Alaska National Interest Lands Conservation Act to help preserve the wilderness quality of this special area.

After clearing the Valdez Narrow, the harbor pilot disembarked, and the *Exxon Valdez* entered the outbound, southward shipping lanes. These well-charted and clearly marked lanes, which hug the western side of Prince William Sound, were created by the U.S. Coast Guard to control traffic into and out of the port. The weather was clear (four mile [6.44 km] visibility), although some low clouds and fog were present with only a slight breeze. Captain Hazelwood ordered the ship to accelerate to “sea speed,” or about 20 knots (23 miles per hour or 37 km/h). At around 11:30 p.m., Captain Hazelwood asked permission from port traffic control to divert eastward into the northbound, or incoming, sea-lanes to avoid floating ice that had been reported as present in the southbound lanes. It was a prudent request, although, since then, some experts have suggested that a better plan would have been to reduce speed and maneuver his way through the ice floes. Nonetheless, port traffic control gave Captain Hazelwood permission to change course as there would be no incoming ships in those lanes for several more hours, and the *Exxon Valdez* steered eastward. Hazelwood’s plan was to sail through a mile- (1.6 km-) wide gap in the ice floes, between the eastern edge and Bligh Reef, a series of submerged rocks along the far eastern edge of the northbound, or incoming, shipping lanes. Once through the ice, the *Exxon Valdez* would turn quickly westward and reenter the southbound shipping lanes. Because this maneuver required expert timing and impeccable navigation for a ship longer than three football fields, it is difficult to understand why Captain Hazelwood left the bridge and turned over control to a relatively new third mate, one who did not have the necessary rating to pilot the vessel.

The junior officer had been instructed to turn starboard, or right, back toward the southbound shipping lanes when the navigational beacon on a small patch of rock called Busby Island was spotted. With his attention divided between trying to spot the leading edge of the ice floe on radar and worrying about when to start the turn, the relatively inexperienced third mate missed the Busby Island light

(opposite page) Map of Prince William Sound, Alaska, showing the shipping lanes in and out of Valdez, Alaska, and the route that the *Exxon Valdez* tanker followed when it ran aground and released oil

and, when a crewwoman standing watch near the bow reported that the flashing buoys of Bligh Reef were coming up fast, the third mate knew he was in serious trouble. He ordered an immediate “hard to

starboard,” but it was too late—at almost full speed the *Exxon Valdez* ploughed 600 feet (182.9 m) up into the rocks of Bligh Reef shortly after midnight on Friday, March 24, 1989.

The collision and subsequent failed maneuvers by Captain Hazelwood to rock the *Exxon Valdez* back off the reef tore holes in the four main cargo tanks, along most of their entire lengths. Along the starboard side of the ship, the double-hulled bottom was ripped open and oil began to pour into the sea. Within 30 minutes of the grounding, more than 110,000 barrels of oil (more than 4.6 million gallons, or 17.4 million L) entered the protected waters of Prince William Sound. Within eight hours, 215,000 barrels (more than 9 million gallons, or 34.1 million L) were discharged. Eventually, almost 260,000 barrels (approximately 11 million gallons, or 41.6 million L), or 20 percent of the *Exxon Valdez*'s cargo of oil, found its way into the sea.

For 10 years, loading and transport of oil at the port of Valdez had occurred without serious incident. Although several localized spills had taken place, one of the most notable that of the BP tanker *Thompson Pass*, which had lost 1,700 barrels (71,400 gallons, or 270,300 L) during a loading operation, most spills were small and able to be readily contained. The *Exxon Valdez* was the first true test of the oil spill response plans that had been developed for the port, and it did not go well. The emergency response barge was in dry dock, damaged in a storm several months earlier and still awaiting repairs. Booms and skimming equipment could not be loaded because they were in a warehouse, and only one equipment operator was available to run the forklift and crane needed to load them onto the damaged response barge, which put to sea despite a crack in its bow. It would take 14 hours for the barge to reach the wrecked ship, and by then the slick covered almost 20 square miles (51.8 km<sup>2</sup>). The *Exxon Valdez* had grounded so close to shore that Alaskan environmental officials were hesitant to allow the use of dispersants for fear that they would result in long-term damage to the local ecology. Lightering, or transfer of the oil remaining on board, was delayed over concerns that the *Exxon Valdez* would capsize and sink if the cargo were removed too quickly and because the portable pumps needed to transfer the oil could not be located. Initially, the calm weather helped keep the slick near the grounded vessel. That changed quickly, however, when strong winds and rough seas began to push the oil toward the shoreline. More than 1,200 miles (1,931.2 km) of rocky beaches were coated with oil by the *Exxon Valdez*'s cargo.

### THE CLEANUP

Throughout summer 1989, Exxon mobilized more than 10,000 workers to assist in the cleanup. Total spill response costs were estimated by Exxon to be

approximately \$2 billion, with the majority of the work completed by September 1989. Although several methods were attempted to control the shoreline spread of oil, including limited use of trial burns and dispersants, most of the removal activities were accomplished through manual recovery. Workers with mops, buckets, and steam cleaners attacked sections of beach and tried to collect the oil physically or dissolve it so that it could be washed back into the sea and captured by skimmer ships waiting just offshore. This technique was not very quick or efficient, and many experts claimed that the associated pressure washing used to push the oil off the beach damaged the sensitive local ecology.

Later studies found that three months after the release of the 11 million gallons (41.6 million L), 6 percent (660,000 gallons, or 2.5 million L) had been recovered by skimming and other sea recovery operations; 18 percent (1.9 million gallons, or 7.2 million L) had either evaporated or been broken down by photodegradation from sunlight; 28 percent (3.1 million gallons, or 11.7 million L) had emulsified and been dispersed into the water column; and almost half (48 percent, or 5.3 million gallons, or 20.1 million L) had washed up on the beaches and shorelines of Prince William Sound. Approximately 250,000 birds were killed, along with almost 3,000 sea otters and 200 harbor seals. Fishing for herring and salmon was banned for that year, and many claim those stocks have not recovered to predisaster levels to this day. Even though few effects of the spill remain visible at the surface, along many shorelines a layer of oil is present only a few inches below the rocky beach cover.

### THE AFTERMATH

Investigations by the Coast Guard, the Alyeska Corporation, Exxon, the EPA, and Alaskan environmental officials distilled the causes of the accident down to several reasons. The primary one was that the third mate failed to execute the ordered westward course correction maneuver in a timely manner. This failure was directly related to fatigue—he was functioning on only a few hours of sleep after supervising oil loading operations—as well as a lack of command support on the bridge. Captain Hazelwood, who had been drinking prior to departure, failed to ensure that the ship was being navigated correctly before leaving the bridge. Contributing factors included Exxon's unwillingness to relieve Captain Hazelwood of command, despite previous knowledge of a substance abuse problem, and the fact that both the Coast Guard and port of Valdez traffic control radars were antiquated and inadequately staffed.

The political and regulatory implications of the spill were far-reaching. The Alyeska Pipeline Company significantly revised its oil spill response procedures and greatly expanded its reaction capability. Sufficient equipment and vessels now are stockpiled to manage spills in the 300,000-barrel (47.7 million L) range quickly and effectively. The U.S. Coast Guard has improved its radar system and strictly forbids ships to change shipping lanes, except in the event of an emergency. Tanker captains also are given a sobriety test one hour before sailing, and a 10-knot (11.5 miles per hour or 18.5 km/h) speed limit is strictly enforced. The U.S. Congress was so incensed by the spill that it quickly passed the Oil Pollution Act (OPA) of 1990. OPA included a clause forbidding any ship that had released more than 1 million gallons (3.8 million L) of oil in a spill ever to enter U.S. waters again. The *Exxon Valdez* was the only ship that met this criterion. After \$30 million in repairs at the same San Diego shipyard where it was built, Exxon renamed the vessel the *Sea River Mediterranean*, and it now regularly transports oil from the Persian Gulf to Europe. It has an impeccable safety record. Exxon, as have many of the major oil companies, also has removed its name from the other ships in its fleet.

The OPA also requires the phasing in of double hulls, not just double-bottomed vessels, docking at U.S. ports. Although a double hull would not have prevented the *Exxon Valdez* spill, the amount of oil released would have been significantly reduced. OPA raised liability limits for oil transporters and established a fund (paid for by a \$0.05 tax per barrel of oil) to help pay for cleanups when the shipowner cannot.

Exxon pled guilty to violations of several environmental laws, including the Clean Water Act, the Refuse Act, and the Migratory Bird Treaty Act. The corporation settled its civil and criminal liability claims with the federal government and the state of Alaska for \$1.025 billion. A 2006 court judgment also ordered Exxon to pay fishermen and residents of

the Prince William Sound area \$2.5 billion in compensatory and punitive damages. Exxon appealed this decision to the U.S. Supreme Court, which ruled in June 2008 that the award was excessive and reduced the amount to slightly more than \$500 million. The bulk of the award would be distributed to the Alaskan fishing industry, with about 20 percent going to lawyers. The 32,677 private party plaintiffs would divide the remaining funds. Joseph Hazelwood had his master's license suspended but not revoked and was found guilty of negligent discharge of oil. He was fined \$50,000 and sentenced to 1,000 hours of community service, of which he served more than five years by picking up trash along Alaskan highways and working in a soup kitchen. The former captain of what was one of the largest oceangoing vessels ever built leads a quiet life, far from the public eye, and reportedly makes his living today working as a paralegal and maritime consultant and occasionally serving as a deckhand on commercial fishing boats.

## **Fairchild Semiconductor San Jose, California 1981 Water Pollution**

Between 1977 and 1983, the 20-acre (8.1-ha) Fairchild Semiconductor (Fairchild) facility in San Jose, California, was one of the leading manufacturers of semiconductors in the United States, making the early 286 and 386 computer chips that powered the beginnings of the information technology revolution. Some of the country's best and brightest minds worked together at the San Jose plant to design and create groundbreaking computer technologies and systems. It was for this reason that it was surprising when they failed to notice that the underground storage tank (UST) used to store waste solvents, primarily 1,1,1-trichloroethane (TCA) and 1,1-dichloroethene (DCE), never seemed to fill up. In late 1981, this tank was found to be leaking, but by then an estimated 60,000 gallons (227,125 L) of spent solvents had been released to the soil and groundwater. As a result of this release, groundwater in a public drinking supply well 1,800 feet (549 m) downgradient of the site became contaminated with TCA at concentrations of up to 7,700 parts per billion (ppb). The drinking water standard for TCA at the time was 200 ppb. This well was taken out of service and eventually sealed (filled with concrete), but other wells in the area remained active. Additional contaminants detected in soil and groundwater as a result of the Fairchild release included perchloroethene (PCE), freon 113, and xylenes.

### **REMEDICATION OF THE SITE**

Once the contamination was discovered, Fairchild entered into a cooperative agreement with the U.S. Environmental Protection Agency (EPA) and the

state of California. The defective tank and approximately 3,400 cubic yards (2,600 m<sup>3</sup>) of heavily contaminated (solvent-saturated) soil were removed and disposed of off-site. After conducting a site investigation to identify the nature and extent of the contamination, Fairchild's Feasibility Study concluded that soil vapor extraction (SVE) was the most appropriate way to clean up the remaining polluted soil.

If soil is contaminated with volatile organic compounds (VOCs), typically by the release of solvents or petroleum hydrocarbons stored in underground tanks, the in situ remedial technology that usually is considered first is soil vapor extraction, or SVE. Pioneered in the early 1980s as an alternative to excavation and off-site disposal of polluted soil, SVE (also known as soil venting or vacuum extraction) reduces the concentrations of volatile constituents adsorbed primarily to the clay and organic particles in the soil. This is done by applying a vacuum to a series of extraction wells that have been drilled into the contaminant mass just above the water table in the vadose zone. A negative pressure is created, forcing air to pass through the contaminated soil and evaporating the volatile constituents. The vapors are captured in the extraction wells and treated at the surface, usually passing through a granulated activated carbon (GAC) filter or afterburner prior to venting to the atmosphere. In some cases, depending upon the geometry of the contamination, extraction wells are installed horizontally across the impacted area.

SVE is most successful when used to remediate soil contaminated with VOCs that evaporate easily, which are those that have a relatively high vapor pressure, greater than 0.02 inch Hg (0.5 mmHg). Vapor pressure is the force exerted by the gas given off by a substance that is in equilibrium with respect

to the liquid or solid phase of that substance at a given temperature or pressure. In other words, vapor pressure measures the tendency of a compound to transfer or move from solid or liquid phase to gaseous phase. An example of a compound with a high vapor pressure is acetone, which was the main ingredient in nail polish remover. Acetone, under standard temperature and pressure conditions, or STP, has a high vapor pressure (229.92 mmHg). It moves quickly from liquid state to gaseous state.

Organic compounds such as benzene (vapor pressure of 100.84 mmHg) and toluene (vapor pressure of 28.47 mmHg), the principal constituents of many industrial solvents as well as gasoline, have high vapor pressures. Released to soil, they quickly evaporate, especially with a little encouragement. This encouragement is provided when an SVE system lowers the atmospheric pressure in the soil and creates a disequilibrium between the gaseous phase and the liquid phase of the benzene or toluene, and, to overcome that disequilibrium, the benzene or toluene changes from a liquid to a gas.

If the ground is water-saturated, VOC dissolves into the water, and Henry's law constant (usually denoted as  $K_H$ ) is used to measure how easily the material (VOCs) evaporates from an aqueous solution. Almost all chemicals dissolve to one extent or another in liquids to form solutions. The solubility

of a compound in a liquid depends on the type of compound it is, the temperature, and the pressure of the gas over the liquid. For example, clean (noncontaminated), well-mixed surface water usually contains about 10 mg/L of dissolved oxygen. How easily the oxygen will be released from the water is dependent on the temperature and pressure of the atmosphere just above the water's surface. The higher the temperature and the lower the pressure, the more easily the oxygen will move out of the water and into the atmosphere. Henry's law constant measures this tendency.

Similarly, organic compounds such as benzene or toluene dissolve to a certain extent in water at standard temperature and pressure. At lower atmospheric pressure, solubility decreases and the compound(s) evaporates into the atmosphere, on the basis of its  $K_H$ . Henry's law constants provide an indication or measure of how readily a substance moves from a liquid solution into a gaseous phase. Benzene has a  $K_H$  of 0.005, whereas toluene's  $K_H$  is 0.007. When the contaminant is dissolved in the groundwater, SVE works best on compounds with  $K_H$  greater than 0.001. The less soluble a compound is in water, the more difficult it is to volatilize.

In designing an SVE system, one of the most important considerations is the radius of influence, or ROI. This is the maximal distance over which

Fairchild Semiconductor wafer production facility in South Portland, Maine, 1999 (AP Images)

an extraction well can generate a sufficient vacuum and vapor flow to induce volatilization and removal of contaminants present in the soil. The shape and extent of ROIs depend on the type of soil, the depth and arrangement of the extraction wells, and the power (rating or size) of the vacuum pumps being used. Usually, extraction wells are placed so that ROIs overlap, to ensure that all contaminated areas are covered by the system.

One technique used by engineers to increase the size and effectiveness of ROIs is to install a surface seal over the area to be treated. These seals, usually plastic membranes but sometimes asphalt or concrete, help reduce surface water infiltration that slows airflow. Surface seals also prevent vertical short-circuiting of airflow. This occurs if air is drawn from other areas of the site and not through the contaminant mass. The lower pressure gradients that occur when a surface seal is used, however, often decrease airflow velocities and typically require the use of bigger, more expensive vacuum pumps.

The SVE system that Fairchild installed at the San Jose site consisted of 39 extraction wells that were designed to have ROIs to treat 42,000 cubic yards (32,111 m<sup>3</sup>) of soil made up primarily of alluvial sand, silt, and clay. Air from the extraction wells was pumped through a dehumidifier and then a carbon filter that adsorbed the solvent-rich vapors. Samples that were taken prior to SVE system startup showed soil with maximal TCA and DCE concentrations of 3,530 mg/kg and 17 mg/kg, respectively. The California Regional Water Quality Control Board (CRWQCB) set a soil cleanup goal for the system based on a total chemical removal rate of less than 10 pounds per day (4.5 kg/day). In other words, when the SVE system stopped removing at least 10 pounds (4.5 kg) of total contaminants per day, the CRWQCB and EPA would consider the soil remediated. This approach was based on risk assessment studies that indicated no significant threats to human health or the environment would be present at or below the 10-pounds-per-day (4.5-kg/day) level.

After seven months of operation, the SVE system had reduced TCA concentrations to 416 mg/kg and DCE concentrations to 2.2 mg/kg. After 16 months of operation, the SVE system had met the cleanup goal and was removing less than four pounds per day (1.8 kg/day) of contaminants. Approximately 16,000 pounds (7,258 kg) of solvent had been removed from the soil, with the most recovery occurring within the first two months. In April 1990, the EPA and CRWQCB agreed with Fairchild that cleanup goals had been met and gave the company permission to

shut down the SVE system. Capital and operating costs for the installation and maintenance of the system totaled about \$4 million.

One of the reasons the Fairchild SVE operated so successfully was that, prior to its installation, a pilot test was run. Such a test consists of the installation, operation, monitoring, and maintenance of a mini-SVE system. One or two extraction wells are drilled and equipped and then operated at different wellhead vacuums over a few weeks or months. ROIs are measured in the field, along with the amount of contaminants being captured by the system. Using these data, more efficient final system design specifications can be developed for the full-scale operation.

The environmental problems at Fairchild's San Jose facility were severe, and SVE was not the only remedial solution implemented at the facility. A slurry wall, connected to an underlying layer of clay, was installed around the perimeter of the site to contain the most heavily contaminated groundwater. Groundwater collected by recovery wells installed behind this slurry wall was pumped to an on-site air-stripping treatment system, and then reinfiltred to help flush remaining contaminants out of the soil. Contaminated groundwater from selected off-site areas also was recovered and treated by the on-site system. These cleanup actions significantly reduced the size of the contaminant plume and the concentration of organic compounds that were present.

For business reasons related primarily to the influx of less expensive chips from Asian manufacturers, Fairchild closed the San Jose plant in 1983. The property has been redeveloped for commercial nonmanufacturing uses, but a legacy of its past remains permanently fixed in the public record. Both EPA and CRWQCB required that the site owners, before selling, include a notice in the property deed alerting prospective buyers that contamination was present in the soil on the site and that its groundwater cannot be used for potable purposes. The deed notice also requires that any future use of the site not interfere with ongoing cleanup activities. This was one of the early uses of an institutional control, a way that allows environmentally damaged property to be returned to productive use but safeguards investors, developers, and end users (workers, shoppers, visitors, etc.) by ensuring that redevelopment occurs in a manner that is protective of public health and the environment.

**Feed Materials Production Center Fernald, Ohio (1989–2007) Water Pollution, Soil Pollution** In late January 2007, one of the largest, most extensive environmental cleanup and restoration projects ever carried out by the Department of Energy was officially declared complete. The beginning of this 18-year \$4.4-billion effort can be traced to a decision made by the Atomic Energy Commission in the late 1940s to build a single facility that could process and refine uranium metal. Until then, uranium processing was carried out at separate facilities in New York, Missouri, and Ohio. At this time in history, the United States was deeply embroiled in the cold war arms race with the Soviet Union, and the development, production, maintenance, and testing of nuclear weapons were critical components of the national defense strategy.

Pure uranium is a dense, silvery white metal that is malleable, ductile, and slightly paramagnetic. The uranium that occurs in minerals and rocks, called natural uranium, is made up of three principal isotopes, uranium 238 (99.3 percent), uranium 235 (0.71 percent), and a trace of uranium 234. Uranium 235 is fissionable; that means that if it is bombarded with slow neutrons, a self-sustaining chain reaction can be produced that releases energy. In order for natural uranium to be useful in a weapon or an energy producing reactor, it must first be enriched

to greater than 90 percent uranium 235. Prior to enrichment, the uranium metal has to be molded or formed into specific shapes and sizes.

## BACKGROUND

The Atomic Energy Commission (AEC) was the first federal agency in charge of the United States nuclear weapons and energy programs. The AEC located its uranium metal processing facility in the small farming community of Fernald, Ohio, about 20 miles (32.2 km) northwest of Cincinnati. Fernald had the perfect combination of available inexpensive, flat-lying land; a skilled workforce; nearby rail access; and an almost inexhaustible supply of freshwater. Using its power of eminent domain, the federal government condemned and purchased 1,050 acres (425 ha) of farmland for the construction of a critical national defense installation, the Feed Materials Production Center, or FMPC.

Operational in only five months, by 1951, the first on-site building, the Pilot Plant, began to test methods to develop high quantities of high-purity uranium ingots (bars), derbies (canisters), billets (slabs), and fuel cores (rods) for use in nuclear weapons and nuclear reactors. Eventually, production activities were centered on a 14-acre (5.7-ha) section of the property. From the mid-1950s through the early 1960s, almost 12,000 tons per year (10,886 metric tons per year) of uranium metal was processed. Expanding to 10 major buildings or plants, FMPC

**Waste storage tanks, Feed Materials Production Center near Fernald, Ohio, 2001 (DOE Photo)**

employed 2,900 people and operated 24 hours per day, seven days per week.

Uranium ore was delivered by rail, sampled and classified by uranium concentration, and transferred to silos or drums. The ore then was converted to high-purity uranium trioxide by digestion in acid, chemical extraction, and denitrification. Next, the uranium trioxide was chemically reduced to uranium dioxide by treating it with hydrogen. This material, called brown oxide, then was reacted with anhydrous hydrogen fluoride to form uranium tetrafluoride, or “green salt.” The next step in the processing cycle was to transfer the green salt to Plant 5 or 6, the metal production plants. It was these large hangarlike buildings that formed the heart of FMPC. Fed into industrial furnaces, the green salt was mixed with magnesium and thermally treated to form uranium metal derbies. These derbies then were loaded into graphite molds, melted, and poured into specified shapes (ingots, bars, etc.). Finished cutting and milling were done in other areas of FMPC or sometimes shipped to other facilities and then returned before the final product was sent to the Department of Energy (DOE) facility in South Carolina or Washington State for enrichment. FMPC also processed thorium and accepted uranium from other facilities for recycling into its own production operations. These processes produced 187,400 tons (170,000 metric tons) of uranium metal for more than almost 40 years and were an essential part of the U.S. nuclear defense system.

### POLLUTION OF THE SITE

National Lead of Ohio (NLO), a wholly owned subsidiary of National Lead and a major government contractor, ran FMPC for most of its operational life. Working under tight security and with a high level of secrecy during its production years, NLO received numerous awards for worker safety, manufacturing efficiency, and cost-effectiveness at FMPC but, as in many of its private sector industrial counterparts, not much attention was paid to environmental protection.

During the late 1970s and early 1980s, awareness of environmental issues grew, and the lessening of cold war tensions significantly reduced the need for facilities such as FMPC. As the veil of secrecy that had surrounded—and, to a certain extent, shielded—the operational history at FMPC began to be lifted, it became apparent that facility operations had resulted in several serious environmental and public health consequences. Uranium metal and other site-related contaminants were present in

soil, groundwater, and buildings on the site, and, in several cases, uranium in the groundwater had migrated to off-site areas, including private wells being used for potable water.

The demise of FMPC began in 1984 when the DOE announced that almost 300 pounds (136.1 kg) of uranium oxide had been released into the atmosphere from one of the dust collectors in Plant 9, the building where casting of oversized uranium ingots was performed. Following shortly was a second disclosure by DOE that groundwater from three nearby residential wells contained uranium at levels above water quality standards and that this contamination had been known to be present since at least 1981. Finally, in 1986, DOE admitted that there had been an unauthorized release or venting of radioactive materials from two waste storage silos and that a dangerous crack had been discovered in a Pilot Plant process vessel.

Within weeks, stories were aired on *60 Minutes* and *20/20*, and newspaper and television reports were being widely distributed about FMPC operations in Britain, Canada, Japan, and Germany. As public concerns grew, the U.S. Environmental Protection Agency (EPA) and Ohio Environmental Protection Agency (OEPA) launched their own environmental investigations into FMPC waste management practices. Over the next several years, the extent of the environmental and potential public health impacts became more frightening.

### A LEGACY OF POLLUTION

For many years, FMPC had difficulty with the effective maintenance and operation of its dust collectors. They were designed to trap and remove airborne particles of uranium released during heating and milling operations. The dusts and fumes were acidic and the baghouses and cyclones used for particulate control tended to corrode and become inoperative. Once released, the uranium dust followed local wind patterns and was deposited as fallout and precipitation washout both on FMPC property as well as on nearby farmlands and pastures. Almost 1 million pounds (453,592 kg) of uranium dust was thought to have been released into the atmosphere by FMPC.

The Great Miami River and its tributaries flow across a series of porous and permeable glacially derived sands and gravels that recharge the Great Miami Aquifer. This aquifer provides drinking water to more than 500,000 people in a 15-county region of Ohio. The Great Miami is one of the 10 largest rivers in Ohio and merges with the Ohio River near Cincinnati. The Great Miami River is an important drinking water resource in its own

right, but underlying FMPC, and extending across much of this part of southwest Ohio is a complex, buried-valley aquifer system that is recharged, in part, by infiltration of water from the Great Miami River and its tributary, the Little Miami River. This water-bearing zone, called the Great Miami Aquifer, is an EPA-designated sole-source aquifer; that means that it is the primary source of drinking water for almost 2 million people who live above it. The aquifer is present in bedrock valleys carved from Silurian and Ordovician limestone and shale, and then filled with coarse-grained sand and gravel. Wells tapping the sand and gravel deposits can produce more than 1,000 gallons per minute (3,785 L per minute), and water can be found as close as 20 feet (6.1 m) below the surface.

Discharges of uranium from FMPC's wastewater treatment plant resulted in the contamination of surface water and sediments within the Great Miami River. A total of 200,000 pounds (90.7 metric tons) of uranium may have been discharged to the Great Miami River and a tributary (Paddy's Run Creek) by surface runoff and through FMPC's wastewater treatment plant.

In addition, FMPC opened six waste pits on its property for disposal of off-spec products, sludge and debris containing residual amounts of uranium, as well as other types of chemical waste. Although it was buried in a thick layer of glacial clay that covered most of the site, the cover on these waste pits allowed the infiltration of rainwater. The pits filled up with water (the "bathtub effect") and either overflowed or leaked into Paddy's Run, an adjacent creek. The contaminated runoff then washed downstream and either discharged into the Great Miami River or seeped into the underlying aquifer. Groundwater contamination also was present underlying many of the FMPC process buildings.

### THE CLEANUP

To alleviate public concerns, DOE replaced NLO as the operating contractor in 1986 with the Westinghouse Material Company of Ohio, a subsidiary of Westinghouse Electric Corporation. DOE also entered into an agreement with the EPA to begin a comprehensive set of site investigation and remedial activities. These measures, however, were too little and too late. The pollution problems coupled with a decline in demand for the material it produced, resulted in the final closure of the facility in 1989 and the cessation of all production operations.

To facilitate regulatory interactions and procedures with the EPA and OEPA, FMPC was added to the National Priorities List by the EPA as a Super-

fund site in 1989, and a series of short-term, interim remedial measures were implemented designed to address the highest-risk areas while more comprehensive studies began to develop longer-term remedial solutions. The name of the site was changed in 1991 to the Fernald Environmental Management Project (FEMP) to indicate the new mission of site operations, and, although it would take many years, the trust and confidence of most local residents and regulatory agency personnel in the objectives and methodologies of the cleanup were reestablished.

Over the next 18 years, DOE and its contractor, Fluor Fernald, demolished more than 100 on-site structures, removed millions of tons of highly contaminated soil and radioactive wastes, and constructed a special 110-acre (44.5-ha) secure disposal area to hold low-hazard materials that do not pose a significant ecological or public health risk safely. A recovery and treatment system was installed to contain and remediate the contaminated groundwater plume present in the Great Miami Aquifer. This approximately 30-well system will operate into the next decade, extracts 4,000 gallons of groundwater per minute (15,142 L per minute) from the Great Miami Aquifer, and discharges the treated water to the Great Miami River. As part of remedial efforts, a public water supply system was extended to those residents whose supply wells had been contaminated by discharges from FMPC. Groundwater monitoring will continue to be performed in order to verify the effectiveness of the extraction and treatment system until uranium concentrations are reduced to acceptable levels.

### THE AFTERMATH

Fernald area residents who sought compensation for emotional distress and decreased property values filed a class action lawsuit against DOE and NLO in 1984. Without admitting fault or negligence, DOE settled the suit in 1989 for \$78 million for commercial and private property within a five-mile (8.1-km) radius of FMPC. NLO suffered no penalty because the federal government was required, under its operating contract with NLO, to protect, or indemnify, them from these types of lawsuits and claims.

The final end use of the property, however, was intended to underscore the seriousness of DOE's commitment to Fernald's environmental restoration. Rather than some sort of industrial or commercial use, DOE has attempted to restore this former 1,000-acre (405-ha) parcel to its preuse, natural condition. A total of 400 acres (162 ha) of woodlots was designed and cultivated, 330 acres (133.6 ha) of seeded prairie, more than 140 acres (56.7 ha) of open water and

wetlands, and 30 acres (12.1 ha) of savanna. The FEMP is now an undeveloped park, designed to provide a venue for the viewing of wildlife with an education and community center intended to enhance the understanding of Ohio's ecology and environment, including the history and operation of FMPC.

**Floridan Aquifer** The Floridan Aquifer is one of the major regional aquifers in the United States. It covers the entire state of Florida and parts of Alabama, Georgia, South Carolina, and even the edge of Mississippi. Its great thickness and underground cave system allow it to store immense quantities of groundwater. The karst topography, however, produces a pronounced environmental hazard in that agricultural runoff and industrial effluence enter the groundwater system directly through sinkholes and are not filtered naturally. Although it is a great source of water, the Floridan Aquifer is delicate and subject to a number of environmental problems.

#### DIMENSIONS AND UNITS

The Floridan Aquifer underlies an area of about 100,000 square miles (256,000 km<sup>2</sup>) within the Atlantic and Gulf Coast Coastal Plain. It is generally thinner to the north, where it is no more than 250 feet (77 m) thick in Georgia and South Carolina. To the south in Florida, it is up to 3,400 feet (1,046

m) thick, especially within the Gulf Trough, a fault-bounded graben.

The Floridan Aquifer is all limestone that mainly ranges in age from about 65 million years to about 20 million years old. It is composed of three units in most places, the Upper Floridan Aquifer, the middle confining unit, and the Lower Floridan Aquifer. The middle unit prevents mixing of water between the upper and lower aquifers. Through most of the area, the upper unit is overlain by a sequence of sand, clay, and limestone that ranges from a few feet thick in central Florida to more than 250 feet (77 m) thick in northeastern Florida and southeastern Georgia. This unit confines the upper aquifer in several large areas, allowing it to become pressurized. In southern Florida, there is a unit in the lower aquifer called the boulder zone. It is formed by a huge cave system with a vertical height of up to 90 feet (28 m). This zone is very deep, up to 3,400 feet (1,046 m) below sea level.

#### WATER FLOW

Recharge of the Upper Floridan Aquifer occurs in generally unconfined upland areas with good drainage, primarily along its northern edge but also in northwestern Florida. Poorly developed streams and abundant sinkholes provide the pathways to recharge. Where the overlying confining layer is 100 feet (30 m) thick or more in northeastern Florida and most of Georgia, recharge is poor.

Natural discharge from the Upper Floridan Aquifer occurs from the plentiful springs. There are as many as 33 first-order springs in Florida with discharge in excess of 100 cubic feet (3 m<sup>3</sup>) per second, or 64.6 million gallons (245 million L) of water per day. In all, there are about 800 natural springs with about 90 percent of them in Florida. Total discharge from these abundant springs is estimated at eight billion gallons (30 billion L) per day.

The Lower Floridan Aquifer is not well known because it is too deep in many areas. The water movement is considered sluggish in most places except where it is connected to the upper aquifer. It is in these areas that most recharge takes place. Discharge is only through wells and is sparse in central and northern Florida. In most areas, only the upper aquifer is drilled in order to provide water.

#### WATER USAGE

The Floridan Aquifer was first recognized for its potential as a source for water in the 1930s. By the 1940s, it was regularly drilled, and its use was continuous and increasing. By 1950, consumption

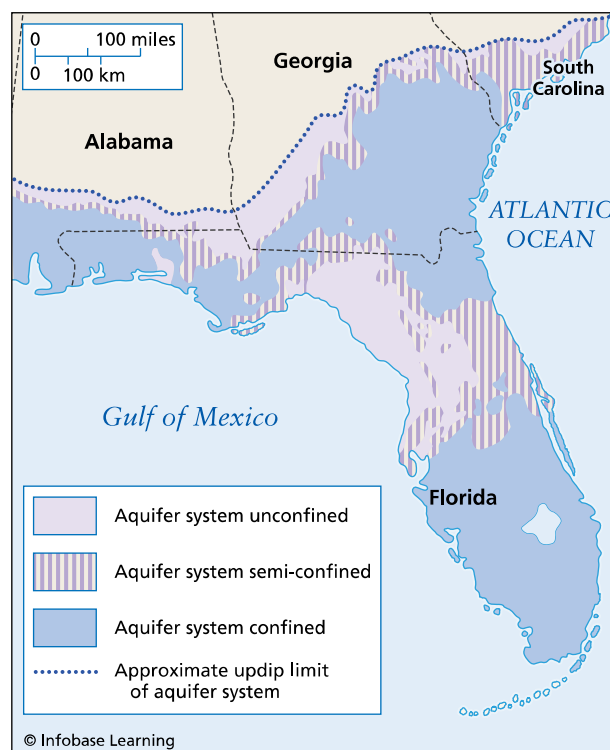

was 630 million gallons (2,394 million L) per day including 90 million gallons (342 million L) per day for irrigation. Between 1950 and 2000, the water withdrawals from the Floridan Aquifer increased by more than 500 percent. In 2000, it is estimated, 4,020 million gallons (15,275 million L) per day was withdrawn from the Floridan Aquifer from producing wells. About 78 percent of this consumption, or about 3,125 million gallons (11,875 million L) per day, was in Florida, whereas it was 825 million gallons (3,135 million L) per day in Georgia, 63 million gallons (239 million L) per day in South Carolina, and 7 million gallons (27 million L) per day in Alabama. Mississippi did not consume any water from the aquifer. About 90 percent of the water consumption was from the upper aquifer. About 8.2 million people consumed the water withdrawn for public water supplies, whereas about 1.6 million people consumed water from private wells.

### PROBLEMS WITH WATER QUALITY AND QUANTITY

With all of this consumption, it is no surprise that the water table is rapidly declining in the shallow Floridan Aquifer. In southern Georgia and northeastern Florida, water levels have declined about 0.3–0.5 foot (9–15 cm) per year since 1950. In the Florida Panhandle, levels dropped 100 feet (31 m) between 1950 and 2000, forcing several towns to relocate their well fields. This decrease in water has dropped lake levels, dried up wetlands and swamps, and reduced the flow rates in many springs or stopped them completely.

The reduction in quantity has also had a negative impact on quality. In many coastal areas such as Hilton Head, South Carolina, and Pensacola, Florida, among others, the withdrawn freshwater has been progressively replaced with salt water from the ocean. Previously, the vast freshwater flow took it right to the coast. Saltwater incursion in many areas is impacting private and public wells and threatens to disrupt the tourism industry. Wells have to be drilled inland to compensate, but the draw keeps pulling the salt water farther inland as well.

Pollution of the aquifer from human sources is rampant. In many areas, sinkholes form an open passage from surface water to groundwater. Dry sinkholes are commonly used as dumps in rural areas, where rainwater leaches through waste to deliver leachate directly into the groundwater system. Flooded sinkholes form lakes and ponds that are desirable building locations. Overflow from septic systems and runoff carrying fertilizers and pesticides from lawn and landscaping flow into these water bodies, which are

**Map of the Floridan Aquifer system in Alabama, Georgia, Florida, and South Carolina**

directly connected to the groundwater system. Agricultural runoff also carries pesticides and fertilizers into the sinkholes. As industry has followed the population boom in Florida and Georgia, it too contributes industrial chemicals to the mix. The water quality in the Upper Floridan is degrading at a rapid pace. Pesticides, herbicides, and fertilizer are now detectable in most of the water taken from the upper aquifer. Some towns are starting to draw from the lower aquifer, but it is saline and not potable through much of the area. This situation will worsen as consumption increases.

The Floridan Aquifer flows groundwater through a cave system. Normally, groundwater is purified by filtration through the small grains of common sediments. Caves transmit groundwater with virtually no filtering or chemical purification at all. They are simply large pipes. For this reason, the Floridan is particularly sensitive to pollution.

**formaldehyde** Formaldehyde is one of the most widely recognized industrial chemicals, both in terms of the name and the sickly sweet smell and because it is used as a preservative for biological specimens such as fetal pigs and frogs. It is also widely recognized as a preservative for recently deceased people so that the corpse will not begin to decay before the funeral. Even though it is best known for these uses, they are minor in comparison to the industrial use of formaldehyde. It is from these sources that formaldehyde may be a pollutant. The most recent example occurred when the trailers issued to survivors of Hurricane Katrina by the Federal Emergency Management Agency (FEMA) in 2005 and 2006 began to have unhealthy levels of formaldehyde detected in them. The reason was that it was evaporating from the construction materials inside the trailers in the hot southern sun. Indeed, formaldehyde's greatest threat is as an indoor air pollutant that emanates from industrial products.

Formaldehyde is also known as methanal, methylene oxide, oxymethylene, methylaldehyde, and oxomethane. Formaldehyde is available in the United States as its cyclic trimer under the name trioxane and as paraformaldehyde. Formaldehyde has been found in only 26 of the first 1,428 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List). It is the widespread extent and danger as an indoor air pollutant that

led it to be ranked number 244th of the worst 275 pollutants on the 2007 CERCLA Priority List of Hazardous Substances.

### PROPERTIES, USE, AND PRODUCTION

Formaldehyde is an organic compound and a volatile organic compound (VOC) that is naturally occurring and synthetically produced for industrial purposes. In pure form, it is a colorless, flammable gas at room temperature with a pungent, distinct odor. Most formaldehyde is available as a solution, known as formalin, which contains 30–50 percent formaldehyde with 0.5–15 percent methanol. Another available form is trioxane, a crystalline solid with a chloroformlike odor. The primary use of formaldehyde is industrial in the production of chemical resins (57 percent), acetylenic chemicals (12 percent), methylene diisocyanate (6 percent), pentaerythritol (5 percent), urea-formaldehyde concentrates (4 percent), hexamethylenetetramine (4 percent), and miscellaneous products such as chelating agents, nitroparaffin derivatives, and textile treatments (12 percent). These and other formaldehyde-related chemicals are used in the production of fertilizer, paper, plywood, sugar, and well-drilling fluids. They are also used in iron foundries, in agriculture as a preservative for grains and seed dressings, in the rubber industry in the production of latex, in leather tanning, in wood preservation, and in photographic film production. Formaldehyde is also used in relatively small quantities for preservation and disinfection. These include disinfecting hospital wards, homes, ships, storage houses, utensils, and clothing. It is used for preserving and embalming biological specimens; for sterilization of soil; as an insecticide, germicide, and fungicide; and as an antibacterial agent in soaps, shampoos, deodorants, hair preparations, lotions, cosmetics, mouthwashes, and nail products.

Formaldehyde has been produced commercially since the early 1900s and has consistently ranked among the top 25 highest-volume chemicals produced in the United States in recent years. Annual production was 1.87 billion pounds (848,000 metric tons) in 1960 but increased to 11.3 billion pounds (5.14 million metric tons) by 1998. Formaldehyde imports to the United States were about 2.5 million pounds (1.1 million kg) in 1978, 16.2 million pounds (7.4 million kg) in 1983, and 8.5 million pounds (3.9 million kg) in 1985. Imports then increased to 87 million pounds (39.5 million kg) in 1994, 140 million pounds (63.6 million kg) in 1997, and 62 million pounds (28.2 million kg) of formaldehyde and 18.3 million pounds (8.3 million kg) of paraformal-

dehyde in 2000. In contrast, exports were 25 million pounds (11.4 million kg) in 1994 and 17.4 million pounds (7.9 million kg) in 2000.

### ENVIRONMENTAL EXPOSURE AND FATE

Formaldehyde is naturally produced in small amounts in the human body as a part of normal metabolism. A major source of formaldehyde exposure is smog in the lower atmosphere. Exhaust from cars without catalytic converters or those using oxygenated gasoline contains formaldehyde. Automobile exhaust is a major source of formaldehyde in ambient air. In indoor air, formaldehyde is in tobacco smoke and is emitted from gas cookers and open fireplaces. Cigarettes may contribute as much as 10–25 percent of the indoor exposure. It is also used as a preservative in foods, such as some types of cheeses, dried foods, and fish. Some people are exposed to higher levels of formaldehyde if they live in a new mobile home, as formaldehyde is given off as a gas from the manufactured wood products used in these homes.

By far, most formaldehyde is released to the air. Formaldehyde dissolves easily in water, but it does not last a long time because it evaporates or is broken down by microorganisms and is not commonly found in drinking water supplies. According to the EPA Toxic Chemicals Release Inventory (TRI), the annual environmental releases of formaldehyde totaled 17.2–24.9 million pounds (7.8–11.3 million kg) between 1988 and 1999 with the majority (50–66 percent) released to the atmosphere. Releases for 1999 were approximately 24.2 million pounds (11 million kg) from 849 facilities. In 2006, total releases were 21,492,962 pounds (9,769,528 kg).

### HEALTH EFFECTS FROM EXPOSURE

There are several adverse health effects from exposure to formaldehyde. Symptoms from acute exposure at low levels include irritation of the eyes, nose, and throat, along with increased tearing. Severe pain, vomiting, coma, and possible death can occur after drinking large amounts of formaldehyde. Skin can become irritated by contact with a strong solution of formaldehyde. There are not any specific effects from long-term chronic exposure to formaldehyde except an increased incidence of cancer.

Laboratory rats exposed to high amounts of formaldehyde in air for life had an increased chance of developing nose cancer. Some studies of humans exposed to lower amounts of formaldehyde in workplace air developed more cases of cancer of the nose, sinuses, and throat (nasopharyngeal

cancer) than expected. There is also some evidence for excess risk for brain cancer, largely seen among morticians. Rats exposed to high levels of formaldehyde in drinking water had increased incidences of leukemia and forestomach and gastrointestinal tract tumors.

As a result of these findings, the U.S. Department of Health and Human Services (USDHHS) determined that formaldehyde may reasonably be anticipated to be a human carcinogen. The International Agency for Research on Cancer (IARC) determined that formaldehyde is a probable carcinogen for humans, and the EPA agreed.

### REGULATIONS ON HUMAN EXPOSURE

As a result of these adverse health effects, especially the potential for causing cancer, several federal agencies have imposed limitations on human exposure to formaldehyde. The EPA does not have regulations on formaldehyde in drinking water under the Safe Drinking Water Act because it rarely occurs in water. They do, however, set regulations for manufacturers and inspection stations on how much formaldehyde can legally be produced from automobile exhaust. They also require that any release of 100 pounds (45 kg) or more must be reported to the National Response Center. The Food and Drug Administration (FDA) has regulations about the use and quantity of formaldehyde in foods, soaps, and cosmetics. The Occupational Safety and Health Administration (OSHA) established the permissible exposure limit (PEL) at 0.75 part per million (ppm) in air for any eight-hour period and a 15-minute short-term exposure limit (STEL) at 2 ppm. The National Institute of Occupational Safety and Health (NIOSH) set a limit for occupational exposure of 0.016 ppm for any eight-hour period and a 15-minute ceiling limit of 0.1 ppm. The NIOSH immediately dangerous to life and health (IDLH) threshold is set at 20 ppm. The NIOSH National Occupational Exposure Survey taken from 1981 to 1983 found that 1,329,332 workers were potentially exposed to formaldehyde in the workplace.

**Formerly Utilized Sites Remedial Action Program (FUSRAP) Saint Louis, Missouri 1957–present Soil Pollution** The Formerly Utilized Sites Remedial Action Program (FUSRAP) is a Department of Energy (DOE) initiative that is managed and performed by the U.S. Army Corps of Engineers. FUSRAP was created to address radiological contamination left behind at 46 locations throughout the United States from the early nuclear weapons and energy programs overseen by the Manhattan Engineering District (MED) and Atomic Energy Commission (AEC). Both the MED and AEC were predecessor organizations of the DOE, which currently manages the nation's nuclear weapons and military nuclear energy production activities.

### BACKGROUND

More commonly known as the Manhattan Project, MED was the joint military and scientific effort carried out by the United States, with support from both Canada and the United Kingdom, to develop a nuclear weapon using uranium 235 and plutonium 238. Taking its name from the Manhattan Engineering District of the U.S. Army Corps of Engineers, the administrative center for overall program management, research and production activities were scattered across some 30 sites around the United States. Three top secret scientific "cities," including Hanford, Washington; Los Alamos, New Mexico; and Oak Ridge, Tennessee; were built to support full-scale fabrication of the weapon and its related components. Significant contributions to this wartime program were made at sites in Illinois, Cali-

fornia, Utah, and Colorado. By 1945, shortly before exploding the first of its three fission bombs, MED was responsible for 130,000 employees, had spent more than \$3.2 billion (in 2010 dollars), and was using almost 20 percent of the electricity generated in the United States.

At the end of World War II, the development and use of nuclear technology were transferred from military to civilian control by the establishment of the AEC. Originally charged with making sure nuclear weapons could be used effectively in defense of the country, the AEC also was responsible for encouraging the development of peacetime uses of commercial nuclear power, tools, and by-products. The AEC established the national laboratory system and promulgated regulatory programs to protect the public from the hazards of nuclear material use.

The AEC's dual mission, to control the use and application of nuclear technology tightly while promoting its development, led to severe criticism that the agency was either too protective, developing regulations and restrictions that inhibited beneficial commercial applications of nuclear energy, or not protective enough, establishing radiation protection standards that were too lax in the areas of nuclear reactor safety, power plant siting, and environmental protection. As criticism of the agency grew, Congress abolished the AEC in 1974 and divided its programmatic objectives between the newly created agencies: the Nuclear Regulatory Commission (NRC), now charged with overseeing the commercial use of nuclear material, including commercial power plants, and the Energy Research and Development Authority (ERDA), which eventually became the DOE. Today, the DOE is responsible for operating and maintaining the military use of nuclear materials, as well as ensuring the energy security of the United States. Similarly to MED programs, the AEC programs that were intended to advance the scientific understanding and commercial use of nuclear materials resulted in the contamination of buildings, soil, and groundwater at sites in New York, New Jersey, Ohio, Iowa, and numerous other locations.

Most of the contaminated MED and AEC sites were cleaned up to a certain extent, but the public health and radiation protection standards that were applicable in the 1950s and 1960 do not meet those developed in the 1980s and 1990s. The residual amounts of radioactivity present at these sites needed to be addressed, and, more importantly, in many cases contamination had been spread to other locations, either through building demolition and intentional relocation of contaminated materials to local landfills or by such natural processes

as erosion or surface water runoff. To identify, manage, and address these former MED and AEC commercial and governmental research, development, and manufacturing sites, DOE established FUSRAP in 1974. In 1997, Congress transferred the responsibility for the administration and execution of FUSRAP from DOE to the U.S. Army Corps of Engineers (USACE).

Typical contaminants encountered at FUSRAP sites include low concentrations of uranium, thorium, and radium, with their related decay products. Mixed wastes of hazardous chemicals and radiological wastes also are present at some FUSRAP sites. Although none of the currently identified FUSRAP sites represents an immediate public health threat because the levels of radioactive materials present on them are low, their cleanup is an important step in addressing local community concerns and, in many cases, allowing for the productive reuse of often blighted and abandoned property. In addition, contaminants at these sites will remain radioactive for thousands of years, and long-term, uncontrolled exposure to radiation is not consistent with any public health goal. Remediation has been completed at about half of the FUSRAP sites, and cleanup activities are either under way or being planned for the remaining properties. One part of the country that has benefited from FUSRAP cleanup activities is the area in and around Saint Louis, Missouri.

### THE CONTAMINATION

On December 2, 1942, the following coded message was received at the White House: “The Italian navigator has landed in the new world, the natives are friendly.” The Italian Navigator was Enrico Fermi, and the message signaled that his team of physicists and engineers at the University of Chicago had initiated the first successful self-sustaining nuclear chain reaction in a small reactor called Chicago Pile-1 beneath the bleachers at Stagg Field, the university’s abandoned racquets court. This reaction was powered by uranium oxide produced at the 45-acre (18.2-ha) Destrehan Street Refinery and Metal Plant, the chemical plant and metalworking facility in an industrial area near downtown Saint Louis. The plant was later renamed the Mallinckrodt Chemical Works. Three brothers, Edward, Otto, and Gustav Mallinckrodt, founded the company in 1867 as a manufacturer of fine chemicals for pharmaceuticals. It has since grown to be one of the world’s largest firms, specializing in inhalation therapies, medical imaging products, and prescription medications.

MED contracted Mallinckrodt to process uranium and radium ores to produce the fissionable

materials needed for the development of a nuclear weapon. It was the material from the Destrehan Street plant that was in the atomic bombs used on Nagasaki and Hiroshima. In 1957, AEC ordered Mallinckrodt to cease operations at its downtown location, but between 1942 and 1957, the plant had processed more than 50,000 tons (45,359 metric tons) of uranium and radium ores. Although it was decontaminated after the war according to the 1950-era radiation protection standards in effect at the time, radioactive residuals remained, and this location became one of the first FUSRAP-designated properties, known as the Saint Louis Downtown Site.

In 1946, shortly after the end of the war, with the production of nuclear weapons proceeding at breakneck pace, MED purchased 21 acres (8.5 ha) north of the Saint Louis airport for the storage of process by-products containing radioactive residuals from the downtown Saint Louis Mallinckrodt plant. Most of the wastes and residues are stored on open ground, but some contaminated materials and scrap are buried at the western end of the property as well as other parts of the site. Adjoining parcels became contaminated when radioactive materials were washed or blown off the uncovered waste piles. This storage area became the second Saint Louis FUSRAP location, named the Saint Louis Airport Site.

### CLEANUP ACTIVITIES AND CONTAMINATION

In the early 1960s, uranium processing residues and wastes stored at the Saint Louis Airport Site, which also contained several other types of valuable minerals such as copper, were sold by AEC to Continental Mining and Milling Company for reclamation. Continental moved these materials to its reclamation facility in Berkeley, Missouri, but sloppy handling and transfer procedures resulted in the spread of contamination along the haul routes. Those parcels impacted by the relocation of the Saint Louis Airport Site residues became the third FUSRAP designated area, the Saint Louis Airport Vicinity Properties. The reclamation plant where the wastes were shipped and stored was designated the fourth FUSRAP location, the Hazelwood Interim Storage Site.

Once the residuals were relocated to Hazelwood, the existing structures at the St. Louis Airport Site were demolished and buried. They included about 60 truckloads of scrap metal and building debris, along with a vehicle. Up to three feet (1 m) of clean fill (soil) was spread across the surface, in order to meet acceptable radiation exposure levels at the

surface. After the waste piles were removed and remaining contaminated materials buried, the AEC transferred the property to the Saint Louis Airport Authority for reuse. Before this, however, the last of the on-site waste, made up primarily of uranium coprecipitated with barium sulfate, was mixed with topsoil and sent to the Saint Louis County landfill for disposal.

In 1976, the NRC surveyed the Hazelwood Interim Storage Site and found residual uranium concentrations, thorium concentrations, and gamma radiation exposure levels present at concentrations above guidelines for release of the property for unrestricted reuse. This triggered a series of studies and investigations over the next two years that found similar levels of radioactivity at the Saint Louis Airport Site and the associated vicinity properties, including several drainage ditches and Coldwater Creek near the Hazelwood facility designated the Latty Avenue Vicinity Properties.

Another FUSRAP site directly related to the Saint Louis properties is the Madison Site. This is an active aluminum and magnesium metal extruding facility across the Mississippi River from the Saint Louis Airport Site, in Madison, Illinois. Formerly a division of Dow Metal Products, in the late 1950s and early 1960s, Mallinckrodt had subcontracted the Madison plant to perform its uranium extrusion and rod-straightening operations. A 1989 survey indicated that two of the buildings used in this process contained low-level radioactive contamination in dust that had settled on beams and other overhead surfaces. In 2000, the uranium-contaminated dust was vacuumed from overhead structures over a 12-day period. By mid-July, independent surveys confirmed that the Madison Site had been successfully decontaminated. A total of 40 cubic yards (30.6 m<sup>3</sup>) of waste was packaged and shipped to a licensed out-of-state disposal facility. In 2002, the buildings at Madison subsequently were removed from the list of FUSRAP sites. Cleanup of the other St. Louis FUSRAP sites is not as simple, as remedial solutions are essentially limited to excavation and eventual transfer to a final, secure disposal site.

In 1984, the DOE made an attempt to convert the Saint Louis Airport Site into a permanent disposal facility, or cell, for all FUSRAP-related wastes. This plan met with strong resistance from both local area residents and city government, who refused to turn over the title of the property to the DOE. As the site characterization studies continued, and pressure for action grew, the St. Louis FUSRAP sites were added to the National Priorities List as Superfund sites. At the Saint Louis Downtown Site, between 1995 and 2003, the USACE

directed the excavation and out-of-state disposal of almost 64,000 cubic yards (50,338 m<sup>3</sup>) of contaminated soil and debris. At one point, excavation had to be temporarily halted when unexploded Civil War vintage ordnance was discovered buried in one area of the property. In addition, 60 buildings were decontaminated and demolished.

The Saint Louis Airport Site was the largest repository of FUSRAP-related wastes. In places, contamination extended to almost 20 feet (6.1 m) below the ground surface across the 21-acre (8.5-ha) property. Between 1997 and 2002, more than 200,000 cubic yards (152,911 m<sup>3</sup>) of contaminated soil and debris was removed and shipped to a permitted, out-of-state disposal facility. USACE also has worked to stabilize remaining impacted areas through improvements to site drainage and soil cover.

The Hazelwood Interim Storage Site (HISS) and the associated Latty Avenue Vicinity Properties (Latty VPs) are within a few miles of the Saint Louis Airport Site. Thorium and radium contamination was present in soil up to 18 inches (45.7 centimeters) below the surface at levels in excess of federal guidelines. During redevelopment of the site by its current owner, 13,000 cubic yards (9,939 m<sup>3</sup>) of contaminated material was excavated and stockpiled on the eastern side of the site. Another 14,000 cubic yards (10,704 m<sup>3</sup>) was recovered from cleanups along Latty Avenue in 1984 and 1985. By 2001, more than 24,000 cubic yards (18,349 m<sup>3</sup>) of material was removed from the Hazelwood site and sent in covered gondola railcars for disposal to a permitted out-of-state disposal facility.

Remedial activities are ongoing at the Saint Louis FUSRAP sites, as well as other, similar places around the country, and the ultimate cost of the cleanups has been estimated at \$2 billion. The real cost of America's nuclear arms race cannot be tallied until the final FUSRAP site is released for unrestricted reuse.

clouds appear and slowly build thicker and lower. Rain begins as drizzle and slowly intensifies, lasting up to several days, and clears slowly.

As in the cold front, the rain from warm fronts effectively removes particulate from air. These systems, however, typically do not include as much wind unless closely associated with a low-pressure system. With the warm humid air that builds behind the front, buildup of gaseous pollutants in stagnant conditions may occur soon after passage.

### OCCLUDED FRONT

As a cold front moves across the country, sometimes it can overtake a leading warm front. If the two frontal types combine, they can form an occluded front. In this case, the steep-faced cold front overrides the shallow, wedge-shaped warm front. Cold air hugs the ground surface, forcing the wedge of warm air aloft. A result is that, at the surface, only two cold air masses are felt and temperature remains about the same.

These mixed fronts produce weak results of both cold and warm fronts. As the front approaches, conditions resemble a warm front with the slow building of clouds and rain. The weather can abruptly intensify as the steep cold front part of the front approaches before the rain ends. Occluded fronts tend to move very slowly, and inclement conditions can persist for several days.

**furan** There are many varieties of furan, ranging from the pure form to many varieties of benzofuran and dibenzofuran, which forms a compound class similar to dibenzodioxin, better known as dioxin. Furans are also known as divinyl oxide, tetrole, furan, oxole, 1,4-epoxy-1,3-butadiene, axole, and oxacyclopentadiene. The chlorodibenzofurans, or CDFs, are of special interest because of their pronounced adverse health effects and similarity to dioxins. There are 135 different types, or congeners, of CDFs, which vary in the number and position of chlorine atoms in the structure. Unlike several of the other furans, CDFs have no beneficial use and are simply undesirable by-products of industrial processes. CDFs have been identified in 51 of the first 1,416 U. S. Environmental Protection Agency (EPA)–designated Superfund sites on the National Priorities List. The 2007 CERCLA list of the top 275 most dangerous chemicals includes several CDFs, including octoCDF at number 162, heptaCDF at number 166, pentaCDF at number 168, hexaCDF at number 181, general CDF at number 236, as well as dibenzofuran at number 186, among others. Although furans are not regarded as the most dangerous of chemicals,

as indicated by their rank, their widespread nature and similarity to dioxin, with which they commonly occur, make them potentially very harmful to public health and the environment.

### PROPERTIES, USE, AND PRODUCTION

Furan is classified as a heterocyclic organic compound and a cyclic dienic ether. It is both synthetically produced and naturally occurring in pine resin and sorb trees. In pure form, it is a clear, colorless liquid with an etherlike odor that is flammable and evaporates readily. CDFs, on the other hand, tend to be white solids where they have been able to be isolated. Furan has been mainly used as a chemical intermediate in the synthesis of other industrial chemicals. It is also used in the production of lacquers, as a solvent for resins, and in production of agricultural insecticides, chemical stabilizers, and pharmaceuticals. There is very little information on the production of furan; the United States imported some 9.7 million pounds (4.4 million kg) in 1986. CDFs have no commercial value and as such are only produced in small quantities for research purposes, if at all.

### ENVIRONMENTAL RELEASE AND FATE

Furans are released to the environment in a number of ways. They may be released as point source pollutants from manufacturing, transport, and storage facilities as spills or through improper disposal. They also may be released from point sources as a by-product of oil refining, coal mining, and coal gasification. They are also released in cigarette smoke, wood smoke, and automobile exhaust as a nonpoint source pollutant. Furan is also produced from the distillation of wood. Accidental fires or breakdowns of transformers and electrical equipment that contain polychlorinated biphenyls (PCBs) may produce CDFs. They are also by-products of the manufacture of certain chlorinated chemicals, wood treatment chemicals, some metals, and some paper products. Sludge from wastewater, emissions from municipal and industrial incinerators, and the burning of coal, wood, and home heating oil also contain CDFs as point source and nonpoint source pollution.

When released into the air, CDFs are primarily solid particles but also vapor. Depending upon the CDF, they may remain in the atmosphere and be transported long distances before settling to the ground through precipitation. Some of the airborne CDF is degraded by reaction with photochemically produced hydroxyl radicals. The average duration of CDF in the atmosphere is 10 days or more and lasting up to several months under certain conditions.

If released into the soil, CDFs tend to bind strongly to many types of soil particles and remain fixed, in some cases, for several years depending upon conditions. In some situations, CDFs may leach into the groundwater system, especially in waste sites where concentrations are high. It is more common that CDFs are removed from soils to surface waters by erosion. In surface water, CDFs tend to bind to suspended particles and settle into the sediment, where they may remain for years. CDFs are strongly bioaccumulated by fish and other aquatic organisms to levels tens of thousands times higher than the ambient water levels. When animals or humans eat the tainted fish, they may require a significant dose of CDFs. Studies have also found CDFs in milk and beef. Plants do not uptake CDFs significantly, but they can contain it from atmospheric settling on their leaves and other surfaces. When cattle or other animals eat the affected plants, they can accumulate CDFs. There are no specific studies found on other furans, but because CDFs behave similarly to dioxins, they are expected to follow the same pattern of environmental fate.

### HEALTH EFFECTS FROM EXPOSURE

Exposure to furans of any type can yield severe adverse health effects. Acute exposure typically causes irritation to chemical burns of the skin and eyes through contact. Inhalation can irritate the nose, throat, and lungs, and pulmonary edema is common at higher dosage. The central nervous system is also commonly affected, with headache, dizziness, lightheadedness, unconsciousness, and coma at higher dosage. Very high doses can be fatal. Long-term exposure has been shown to produce weight loss and damage to the thymus, reproductive organs, liver, and kidney, as well as increased mortality rates in laboratory animals.

Acute exposure to CDFs yields similar effects to furan exposure, in addition to chloracne, darkened skin color, swollen eyelids with discharge from the eyes, vomiting, and diarrhea. Longer-term exposure produced anemia, lung infections, numbness, and damage to the central nervous system and liver, in addition to the symptoms of furan exposure. CDFs also caused birth defects, skin problems, and learning and developmental problems in offspring of exposed mothers.

The International Agency for Research on Cancer (IARC) considers furan to be reasonably anticipated to be a human carcinogen on the basis of the results of laboratory testing on animals. It has been shown to increase the incidence of cancer of the liver, adrenal glands, and forestomach, as well as leukemia. Laboratory testing further showed it to be mutagenic to mammal cells, producing chromosomal aberrations and sister chromatid exchanges.

### REGULATIONS ON HUMAN EXPOSURE

Surprisingly, considering the widespread nature and health effects, there are very few federal regulations limiting exposure to furans of all types. The EPA requires that all industrial releases and spills of furan in quantities of 100 pounds (45.5 kg) or more must be reported to the National Response Center. They also consider CDFs to be hazardous waste products.

# G

**Giardia** *Giardia* is a genus of protozoan parasites that is responsible for most intestinal infections in humans in the world. It is widespread in the environment and able to infect mammals, birds, reptiles, amphibians, as well as humans, and is found in beavers, muskrats, wading birds, voles, mice, shrews, gerbils, rats, deer, native marsupials, and humans in the United States alone. Although there are many species of giardia, those that infect humans are *Giardia lamblia* (most common in the United States), *Giardia duodenalis*, and *Giardia intestinalis*. Since monitoring began in 1971, *Giardia* has been the most abundant pathogen in waterborne human disease outbreaks in the United States. Between 1971 and 2000, more than 130 *Giardia* outbreaks were reported in 27 states. As many as 250 of every 10,000 Americans are infected each year, and, between 1979 and 1988, more than 4,600 were hospitalized annually. The World Health Organization estimates that some 200 million people are infected each year worldwide. The reason that it is so widespread is a function of the life cycle and ability to survive in many environmental conditions.

## SOURCE AND DISTRIBUTION

The life cycle of *Giardia* begins when the trophozoite divides by binary fission and attaches to the brush border of the epithelium in the small intestines. They detach after a period and become rounded cysts through exposure to bile in the upper bowel, while building a resistant cyst wall in the lower small intestines. The cysts are then excreted in feces and move passively through the environment, primarily

in water. The cysts may then be ingested by another animal host, where exposure to low-pH conditions in the stomach allows the cyst to advance to the trophozoite stage, and the cycle begins again.

*Giardia* is found worldwide in lakes, ponds, rivers, and streams, and even in high-quality water sources such as springs. All surface waters on Earth probably contain *Giardia*, but they are more abundant in certain areas. The concentrations range from 38,000 to 380,000 cysts per gallon (10,000–100,000 cysts per liter) in untreated sewage, 38–380 cysts per gallon (10–100 cysts per liter) in treated sewage, and fewer than 38 cysts per gallon (10 cysts per liter) in clean surface water and tap water. Animals in agricultural areas are commonly infected, especially calves, lambs, and dogs, and surface waters in these areas have high concentrations. In the United States, the levels are highest in the late summer through early winter. Cysts cannot withstand hard freezing, but they can persist for periods up to two to three months in cold water at temperatures less than 50°F (10°C). They are all killed at water temperatures in excess of 129°F (54°C) within 10 minutes.

People are more commonly infected with *Giardia* if they use surface water sources that are unfiltered, shallow well water systems, or contaminated water for drinking while camping or hiking. They might also be infected by accidentally ingesting water while swimming or engaging in other water-related recreational activities. Poorly maintained wading and swimming pools and heavily recreated ponds and lakes are especially notorious for *Giardia* transmission. Even springs, which are typically regarded as pristine, were found to be 14–19 percent contaminated in separate studies.

### HEALTH EFFECTS FROM EXPOSURE

The incubation period for *Giardia* ranges from 3 to 25 days after exposure, with the most common at 7–13 days. The infection is commonly asymptomatic in children, and even many adults exhibit no symptoms. A great number of people have probably been infected and do not even know it. The most common symptom is diarrhea. It can vary from transient and mild, passing without notice, to severe and/or chronic. Other symptoms include abdominal cramps, bloating, flatulence, steatorrhea (loss of fat in feces), weight loss, and occasional vomiting. Weight loss may be significant, up to 10–20 percent. In some cases, the infection lasts only three to four days (most commonly), whereas in others, symptoms can last for months or even years. There is also a correlation between *Giardia* and pancreatic insufficiency or hepatic cirrhosis, but it is not clear whether the *Giardia* causes the pancreas and liver problems or whether people who have those problems are more prone to *Giardia* infections. Acquired immunodeficiency syndrome (AIDS) and cystic fibrosis patients tend to have more serious and prolonged infections as well.

Most people who are hospitalized for *Giardia* infections are children younger than age five suffering from dehydration, and the length of stay averages four days. Between 1979 and 1988, 66 percent of the hospitalized cases in Michigan were infants of one year or younger. A potential complication of *Giardia* infections in children is nutritional insufficiency, which can lead to growth and developmental problems. Complications can include poor absorption of iron, allergic reactions, inflammation of the synovial membranes in joints, and reversible retinal problems.

*Giardia* is common in child and infant day-care centers. The infection rate has been found to range from 7 to as high as 54 percent in the United States, and even day-care workers are estimated to have infection rates of 9–35 percent. On a worldwide basis, it is estimated that infection among children commonly ranges from 1 to 36 percent but exceeds 68 percent in some countries.

### REGULATIONS ON HUMAN EXPOSURE

The U.S. Environmental Protection Agency (EPA) has set a Surface Water Treatment Rule (SWTR) that public water systems must filter and disinfect surface water as well as groundwater that is directly impacted by surface water. In this process, at least 99.9 percent of all *Giardia* cysts must be removed or killed.

**glacial deposits** There is a general name for all glacial deposits, which is *drift*. If the sediment is carried and deposited by ice, it is called till. If it is carried by meltwater, it is called outwash. Ice can carry any size sediment with the same amount of energy. For this reason, till is very poorly sorted, or, in other words, sediments of all sizes from clay to boulders are typically mixed together. It takes faster-flowing water, however, to carry larger sediments. As water slows, sediments drop out of suspension in size order, larger to smaller. For this reason, sediments deposited by water (outwash deposits) tend to be better sorted, or, in other words, like-sized sediments tend to be deposited together. Outwash is not as well sorted as beach sand, but it is much better sorted than till.

### ICE DEPOSITS

In general, sediments on hillslopes and hilltops (even if plains) are deposited by ice. The general term for most unsorted deposits is *upland till*. There are, however, a few specific deposit types from ice.

### Erratics

Glacial erratics are large boulders commonly sitting perched on bedrock. These boulders can be large

Outwash from glacial streams formed these well-known cliffs at Gay Head on Martha's Vineyard, an island off the coast of Massachusetts. (© Walter Bibikow/Corbis)

as a house and resting on bedrock or perched on small boulders, referred to locally as tripod rocks to reflect their footing. Typically, these erratics will be the only glacial deposits on a scraped bedrock surface. Other erratics appear encased in normal glacial till deposits. These large rocks are more commonly overlooked because their appearance is less dramatic. They simply appear as low swales of rock on the landscape and may be confused for bedrock in some cases.

Glacial ice transports all sizes of material together by encasing them in snow and ice and lifting them off the ground in a mass. As the ice melts, it then releases all of the material in a deposit. Although, in rare cases, a large rock could be dislodged from the ice by subglacial contact with bedrock, it is more commonly dumped with all of the other sediments. For this reason, the erratics encased in till are, by far, the most common. In most cases, the erratics left perched on hills as a single deposit or group of deposits result from the erosion of all of the other till by glacial outwash or later weathering.

### Boulder Fields

In most cases, the glacier did not carry one or a few huge rocks such as those seen in erratics but instead carried a group of boulders in the one-to-six foot (0.3–1.8 m) range. These rocks were carried along and deposited with all of the other sediment sizes. The grinding and scraping of these rocks during transport tended to round their edges. If, sometime after deposition, these mixtures of sediments were subjected to erosion by water, all of the finer material may have been removed, leaving only these rounded boulders behind. The deposit of boulders is called a boulder field and is really an erosional feature.

The formation of a boulder field can be observed in areas where the edge of a till deposit is removed by excavation during a construction project. As the hill face is weathered and eroded, the fine material is removed first, leaving the boulders protruding. At some point, these boulders break loose and roll down to the base of the hill, forming a pile. Although not exactly the same, this is an analogous process to the formation of a boulder field.

### Moraines

A moraine is a much larger feature than an erratic or boulder field, which are small and local. It is a large deposit of till that marks the edge or end of the glacier. Glaciers slowly but continuously move toward areas of higher temperature. At some point, the temperature increase and consequent melting balance the movement speed, marking the end of the glacier. All of the entrained rock and soil is deposited as the ice melts away, leaving a large deposit of till. The duration that this end of the glacier remains in one spot during the conditions of changing temperature determines how extensive the moraine deposit will be. The deposit at the farthest extent of the glacier (to the south or downhill) is the terminal moraine. This is typically the largest moraine because the termination of the glacier remains there longest and can form rather large landmasses such as Long Island, New York. The topography of such moraines can be quite dramatic,

Granite erratic left by retreating glaciers during the Cretaceous period in Enchantment Basin, Washington, near Mount Stuart © Joel W. Rogers/CORBIS

with piles of sediment on the order of hundreds of feet high and miles wide in places.

As the ice retreats during the waning period of an ice age, it does so in stages. It retreats quickly for a distance and then stabilizes for a period. Each time the retreat stalls, a recessional moraine accumulates at the front of the glacier. Recessional moraines are typically much smaller than the terminal moraine and form parallel bands of sediment across the landscape. By definition, these moraines formed parallel to the end of the glacier and perpendicular to the direction of ice flow. Although many glacial features disrupt local surface water drainage, moraine deposits can be the most effective. They create extensive wetlands, ponds, and lakes locally. One reason that drainage is not worse around moraines is that they are generally collocated with outwash deposits, which are generally well drained.

### WATER DEPOSITS

Water is released from glaciers both by heating of the surface by the Sun and by the pressure generated by the weight of the glacier on the base. The pressure is highest where the ice has contact with protruding bedrock. Melting tends to take place at these points similarly to the phenomenon of ice melting beneath the blades of ice skates at the small area of contact that supports the weight of the skater. Just as with ice skating, this melting causes the contact to be slippery and promotes movement. Subglacial meltwater is generated in this way as well as by infiltration of surface meltwater through cracks to the base of the glacier. Some of this infiltrating water may also form and flow through tunnels in the ice at intermediate levels of the glacier. This water may or may not carry sediment. All levels of water exit the glacier and combine at its termination, yielding vast quantities of freshwater. All of these flows produce different glacial deposits.

### Eskers

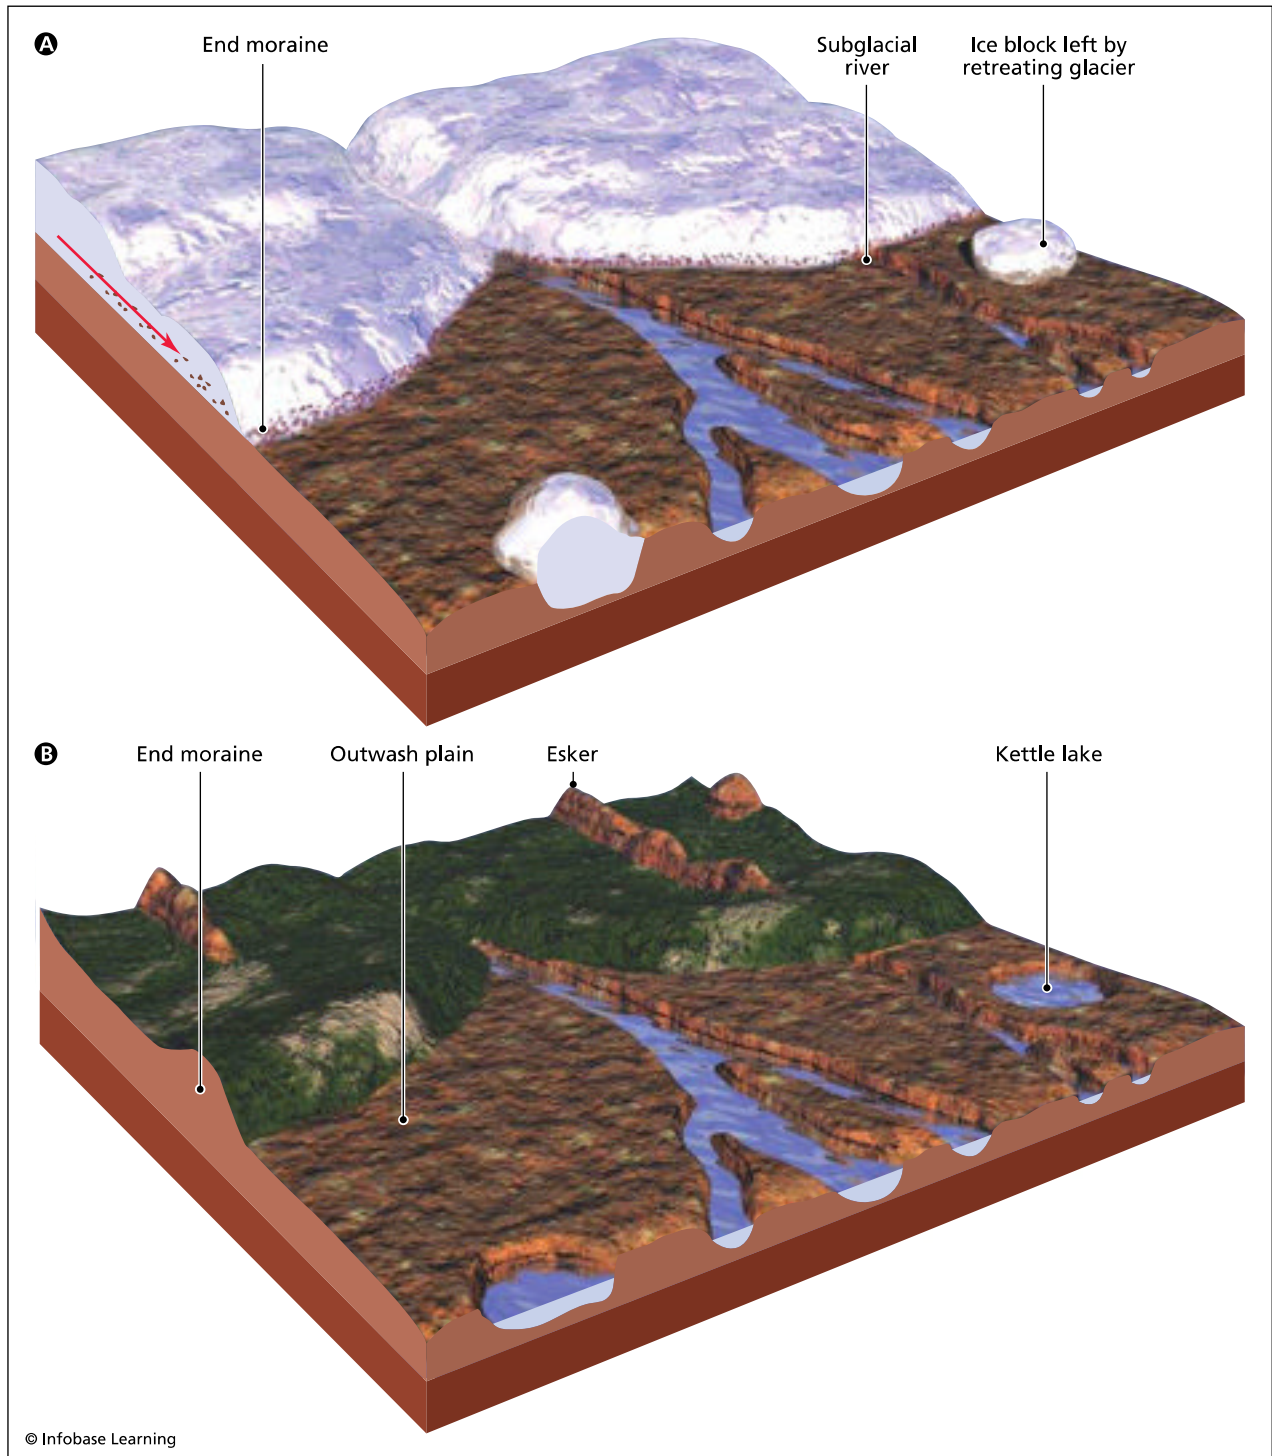

Tunnels form at the base of the glacier within which the subglacial meltwater escapes. Subglacial meltwater washes over the ground surface during its journey and picks up significant amounts of sediment. As the water slows within the tunnel during periods of reduced flow, it deposits the sediments within the tunnel. After the glacier retreats, many of these tunnel fills are preserved as eskers. They appear as long, very narrow ridges up to 30 feet (9.2 m) high and miles long. They look like strands of spaghetti on a map. The sediments within the eskers are relatively

well sorted because they are deposited by water and are generally coarse grained. They are characterized by high porosity and permeability, and as a result, may transmit water and gas freely.

### Glacial Lakes

With all of the meltwater generated at the end of the glacier and disrupted drainage from the moraines, significant glacial lakes may develop. These lakes

**Block diagram (A)** shows the processes at the end of a glacier including generation of meltwater and the entrainment and accumulation of rock, soil, and debris at the melting edge. **Block diagram (B)** shows the results of those processes including an end moraine, an esker filling the former subglacial river tunnel, and an outwash plain from the rivers.

may be tens of miles across and hundreds of feet deep. Because these lakes form in ice ages, they are frozen most of the year. The ice cover eliminates surface input and waves that might stir up the sediment. Sedimentation during this time is restricted to very fine-grained material (clays) at a very slow rate. In the summer months, the ice melts, and slightly coarser material may be deposited both from increased input from higher volumes of meltwater and from increased churning from surface waves. The result is a deposit of very finely interlayered clay and silt, called varves. Each layer is about 0.1 inch (0.25 cm) or less and represents a season. These deposits have extremely low porosity and permeability and are good for containing dangerous materials. In some cases, the lakes may contain significant vegetation, especially in swampy areas, and the deposits may be organic-rich and black in color. These deposits are prized for agricultural purposes.

As the glacier melts at the end, chunks of ice may calve off into the glacial lake and form rafts. These rafts can float all the way across the lake before melting. As they melt, they release any sediment they might be carrying. Large pieces of sediment, such as cobbles and boulders, drop through the water and embed themselves into the varve deposits, typically deforming and disrupting the fine layering beneath. These deposits are called dropstones and are one of the main determining factors in distinguishing a glacial lake from any other lake in a temperate to cold climate.

In many cases, the glacier itself actually forms part of the dam that retains the water in a glacial lake. When the glacier retreats during a warming period, the dam may be broken. The removal of the ice that dams the lake from below the lake bed to the water surface allows the entire lake to drain at once. This draining may produce catastrophic flooding, the likes of which are rare in the history of the Earth. The floodwaters may scour huge canyons and remove huge amounts of sediment in a matter of days. Such catastrophic events have been interpreted for the channeled scablands in western Washington. The massive Glacial Lake Missoula stretched across Washington, Idaho, and Montana. It was 2,000 feet (610 m) deep and 200 miles across (322 km) and contained more than 500 cubic miles (2 billion cubic decameters) of water, or more water than Lake Erie and Lake Ontario combined. It essentially formed an inland sea during the ice ages. When the largest of the ice dams failed, water burst through at a rate 10 times the combined flow of all the current rivers of the world. This flood is documented to have stripped away hundreds of feet of soil and cut deep canyons—coulees—into the underlying bedrock.

This is how the Grand Coulee formed. With flood speeds approaching 65 miles (105 km) per hour, the entire lake drained westward into the Pacific Ocean in about 48 hours. The floods carved out 50 cubic miles (208 million cubic decameters) of earth, piled mountains of gravel 30 stories high, created giant ripple marks the height of three-story buildings, and scattered 200-ton (181-metric-ton) boulders from the Rockies to the Willamette Valley.

### Kame Deposits

Instead of single or dispersed rocks, some of the calved icebergs carried large pockets of sediment. The pockets typically formed as potholes in the ice or part of the intermediate-level tunnels in the glacier. They filled with sediment carried and deposited by meltwater as it lost velocity. In other cases, the sediment may have been moraine material that deposited on glacial ice. In either case, the iceberg rafted the sediment out into the middle of the lake and then melted. The sediment fell to the bottom of the lake in a jumble and deposited on the varved clays of the lake deposits, typically deforming and disrupting them. It is common for these relatively porous and permeable deposits to form perched aquifers.

### Kame Deltas

As meltwater flows from the glacier into the glacial lake, it loses velocity and can no longer carry sediment. As a result, all of the sediment drops out of suspension at the mouth of the stream in the glacial lake, forming a delta. These deltas form similarly to constructive deltas in the ocean. The receiving lake has such small waves that most of the deposited sediment remains at the mouth of the meltwater stream, creating a sizable area of land. The delta has many of the same features as an ocean delta including channels, levees, and channel splays. There are, however, some major differences. Whereas sea level is very slow to change, allowing deltas to remain at a stable elevation for a long period, glacial lakes experience radical level changes from bursting of ice dams—in the lake (lowering), in small lakes above the main lake (raising), or in glacial surge or calving of icebergs into the lake (raising), among others. The radical and significant lake level changes cause the delta to reestablish at various levels, forming terraced delta deposits.

The main glacial lake commonly forms at the foot of the glacier. The position of the termination of the glacier is determined by the interplay of ambient temperature and glacial surge (southward movement). If the temperature decreases or the movement increases, the glacier surges southward and may overrun the lake. The mass of ice deforms the glacial deposits as

well as the lake deposits along the margin, folding, faulting, and contorting the layers. These ice deformation features are common. The constant freezing and thawing of the lake also affect sedimentation patterns. Freezing slows and can stop flow of meltwater, allowing the deposition of clays and other fine-grained materials on the otherwise coarse sands and gravels, forming very distinctive layering.

### Drumlins

It is still debatable as to whether drumlins are deposited by ice or water, but it is likely that their formation is through a combination of the two. Drumlins are elongate features composed of till that are up to one mile (1.6 km) in length, one half-mile (800 m) in width, and more than 160 feet (50 m) in height. The north end of the drumlin (facing the glacier) is steep and elevated, whereas the south end (flow direction) tapers down to ground level. Drumlins are commonly grouped together in swarms in which they overlap each other. Areas with swarms of drumlins are referred to as having “basket of eggs” topography because of their form, though they look more like fish scales. Internally, the deposit is composed of till, but some of the sediment shows evidence of flow, including layering of pebbles and cobbles inclined in the direction of flow (imbrication) and internal sorting locally.

There is some debate about how drumlins are formed; the most widely accepted current idea is that

they were formed when the ice became overloaded with sediment. When the competence of the glacier was reduced, material was deposited. The deposited sediment then appears to have been modified by heavy subglacial flow of meltwater, shaping it into the characteristic drumlin shape. Studies of regional distribution and shapes show that they formed best where the meltwater flowed quickly downhill with ample headroom and deteriorated where the meltwater was forced uphill.

### Roches Moutonnées

Roughly translated as “woolly rock,” roches moutonnées are erosional features formed by scraping of the glacier on underlying bedrock. They look similar to drumlins with a steep side (typically vertical) similar to the hindquarters of a sheep and a sloping, tapered side similar to a sheep head in grazing position. Unlike the drumlin, the roches moutonnées are made of exposed bedrock, and the steep and shallow sides are reversed with the shallow side toward the glacier and steep side away. The shallow side is simply formed from abrasion of the rock surface by materials carried in the flowing ice; the steep side is formed from plucking of pieces of bedrock by the glacier, primarily by breaking along steep joints, thus the steep angle.

## GLACIAL DEPOSITS AND POLLUTION

With so many different types of glacial deposits, no single summary of their properties relative to pollution is possible. Outwash deposits tend to be stratified and well sorted, producing good porosity and permeability. They commonly form shallow aquifers but only in valleys and lowlands, where they can be 100 feet (30 m) thick or more in many areas. Outwash deposits are sparse and thin on hillslopes. The sediments are unconsolidated in these deposits and transmit water well, yielding natural springs in many areas. The high permeability also has its drawbacks, as groundwater is not purified as readily in outwash deposits as it is in other units, and it can be quickly overwhelmed with pollution from overindustrialization or housing development. In this case, the water quality may be compromised.

Glacial till is commonly too thin and so poorly sorted that it does not make a good aquifer. The mix of grain sizes limits the porosity and permeability, making it a poor aquifer. On the other hand, its components of ground-up rock and soil tend to be chemically reactive, and the high clay content filters water well. For this reason, it is generally better at purifying groundwater than the same vol-

**Block diagram showing the formation of drumlins beneath a glacier, with the blue arrows representing subglacial water flow**

ume of outwash deposits. Till can contain mixed-in trees and other vegetation that can rot and produce methane gas that is trapped with the groundwater. There have been cases when this methane has entered homes through the water supply (pipes) and accumulated in indoor air. Methane displaces oxygen in the home and can be toxic to humans and animals, causing suffocation. In water wells that were hand dug, released methane in the well has been known to be fatal. Methane is also highly flammable and has been reported to have blown up homes in Minnesota and other areas when inadvertently ignited. Other glacial deposits, especially related to swamps and lakes, have also been known to produce methane.

Clay deposits, especially in glacial lakes, have a very low porosity and permeability. They are excellent at containing hazardous materials and keeping them sequestered from the groundwater system. This was the case in Love Canal, New York, where the highly toxic substances in the chemical dump would probably have been relatively safe if homes and a school had not been built on top of it and broken through the protective clay cap. It is important that, if such substances are stored in glacial clay, there are no leaks and that the clay is not disturbed. Kame deposits may form perched water tables in glacial clays and must be accounted for before they can be used for waste storage or disposal.

**glaciation** The accumulation of ice and snow on a continuous and long-term basis is glaciation. The precipitation generally falls as snow and is compacted to firn and neve before becoming glacial ice, though melting can enhance the process. There are two types of glaciation, continental and alpine. Both types involve the movement of thick

ice bodies, continuous renewal, and melting. Both types entrain rock, soil, and other debris and form distinctive deposits. Alpine, however, is restricted to the mountains and is typically young, whereas continental is located on relatively flat land in polar regions. It only extends away from those areas during ice ages.

#### ALPINE GLACIERS

Glaciers form in mountains as a function of global climate, elevation, and latitude. As long as a mountain is in an area that receives precipitation (snow) and some part of it remains below freezing for enough of the year to support permanent ice, alpine glaciation will occur. If a mountain is high enough and/or the global climate is cool enough, alpine glaciers can even occur at the equator; such glaciers are not common. Most high mountains have some glaciation. As soon as ice is thick enough, under the force of gravity, it begins to flow downhill very slowly in the zone of transport. As it moves, the ice moves to warmer temperatures at lower elevation, and it melts. In the zone of ablation ice is removed from the glacier by melting. At a certain point, melting back will equal the downward surge of the ice. That point is the end, or termination, of the glacier. The point shifts downhill in winter and uphill in summer and shifts on a longer-term basis with global cooling or warming.

Alpine glaciers are erosional agents at the tops of mountains and depositional agents at the base. Glacial ice forms in an area of accumulation, and, as it moves, it scrapes out the rock and soil beneath it. The scoop-shaped indentation it leaves behind is called a cirque. As the ice scoops out many cirques, they reshape the peak of the mountain as they coalesce into an arête and finally a horn. All of the ice flows that form the cirques flow together as in tributaries of a river to make a larger alpine glacier. Unlike in a river, as they combine, they do not mix but simply add width to the edges of the glacier. Each added glacier from a tributary can even be distinguished within the main glacier. The reason for this is that the edges of the glaciers entrain rock and soil called a marginal moraine. As the glaciers combine, they retain their moraines, and the moraines enter the main glacier as medial moraines. The medial moraines appear as dark stripes on the otherwise white glacial ice, parallel to the flow direction and permanently marking the added tributary glaciers in the main glacier. The glacier bends as it winds its way down the mountain and forms numerous cracks in this process called crevasses.

**Mendenhall Glacier in Alaska** (*Joy M. Prescott; used under license from Shutterstock, Inc.*)

Unlike rivers that form V-shaped valleys through erosion, when glaciers flow down a mountain, they form U-shaped valleys. This is because the weight is spread out over the stiff base. The larger the glacier, the deeper the U-shaped valley. Where the tributary glaciers join the main glacier, they cut much more shallowly into the mountain. Later, when all the ice is melted, these tributary valleys will form shallow hanging valleys on the deep valley wall of the main glacier.

Both the weight of the ice pressing the base on the valley floor and the heat of the Sun will cause the ice to melt. All of this melting means that the termination of the glacier typically has much meltwater flowing out of it. There are typically rivers emanating from the ends of alpine glaciers. In addition, both the ice and meltwater carry a lot of sediment, much of which is dumped at the end of the glacier in a moraine. The piles of sediment may dam up this river and form a pond and/or swamp at the end of the glacier, as well. The exact nature of the sediments and surface waters at the end of the glacier depends upon whether the end of the glacier is in the mountains, at the base of the mountains, in the ocean, or in a large lake.

### CONTINENTAL GLACIATION

Continental glaciers are present today primarily on Antarctica and Greenland. During ice ages, however, they can extend all the way to the midlatitudes. These glaciers operate similarly to alpine glaciers with zones of accumulation, transport, and ablation. Continental glaciers, however, are much larger, forming huge sheets the size of continents. Snow accumulates up to one mile (1.6 km) thick, and the entire mass moves away from the Poles at slow speed.

In the last ice age, continental glaciers extended southward to New York City and across the northern border of the United States. The water to make all of this ice was from the oceans. Sea level dropped some 200 feet (61 m), exposing the continental shelves as land. Previously slow rivers became raging torrents, cutting deep canyons all the way out onto the exposed shelves. The moving glaciers entrained huge amounts of rock and soil and continuously deposited them at the melting southern end of the glacier. Long Island, New York, was formed by this process, as were Cape Cod and Martha's Vineyard and related islands in Massachusetts. As the glaciers melted at their base from overburden pressure and at their tops from sunlight, they formed large subglacial rivers

feeding into huge lakes. Many of the larger lakes drained after the ice age waned, but the Great Lakes and Finger Lakes of New York were formed by these processes. The weight of the ice sheet depressed the crust of the Earth into the mantle during the ice age, actually lowering the surface elevation.

Most of the features we see today along the coasts and the northern part of the United States are the result of the last ice age. There is a sharp demarcation across the northern part of New Jersey, to the north of which there are numerous lakes and to the south of which there are few, if any. This line can be traced across the United States where states to the north such as Minnesota, which boasts 10,000 lakes, have poor drainage from glacial deposits and states to the south may have no lakes. All rivers widen at the coast, have deep bases, and are estuaries with tides pushing ocean water far up their course. The Hudson River of New York is classified as a fjord; it has a bed more than 200 feet (61 m) below sea level in several areas, in which brackish water has been found as far north as Troy, New York, more than 100 miles (160 km) upstream.

The rising sea level from the melting glaciers, once again, flooded the continental shelves. Trawlers off Long Island sometimes recover mammoth bones. As the seas rose, the ends of the rivers were submerged and the old valleys now form submarine canyons along the coast. The sea level rose faster than the coastal beaches could retreat landward. In most cases, sea level overtook the beach and flooded behind it, creating the system of barrier islands separated from the mainland by lagoons or bays that now characterizes the East Coast and Gulf Coast of the United States. The land level is slowly rising, or rebounding, since the weight of the glacier was removed. Structures that were built on the coast several hundred years ago are now well inland. Perhaps the most impressive example of rebound is in Lake Champlain, New York. When the glacier retreated, the land was so depressed that ocean water connected through the Saint Lawrence Seaway and into the lake. As the surface of the land emerged, Lake Champlain was cut off from the ocean, but whale bones and other evidence of marine life can still be found preserved in the sediments of the now-freshwater lake.

### POLLUTION AND GLACIERS

Glaciers have nothing to do with polluting the Earth. They are, however, excellent recorders of global anthropogenic influence, at least in the polar regions. Snow falls on the continental glaciers every year and is preserved as glacial ice. As the snow is created and falls through the atmosphere, it samples

the chemical makeup. There is much information on climate variations and atmospheric chemistry stored in the ice, and there is now a record for hundreds of thousands of years. Scientific teams drill holes in the ice and retrieve continuous cores that are studied in the laboratory.

One use of ice core study is to see whether anthropogenic chemicals are present. If pesticides or industrial chemicals that do not occur naturally appear in glacial ice, they indicate that they are so abundant in the atmosphere and so long-lived that they occur in all air on a global scale. These data were used to help eliminate the use of some of the more persistent pesticides. Chemical pollutants that are both naturally occurring and synthesized occur throughout the cores. By comparing concentrations of a pollutant in ice prior to the industrial age with that in current glacial snow, the relative influence of humans on accumulation of the pollutant may be evaluated. For example, Pat Patterson compared the abundance of lead in glacial ice from preindustrial times with that in glacial snow from the 1960s to show that concentrations in polar regions were 100 times greater than natural levels. Considering how dense lead is and consequently how quickly it settles out from air, levels near the sources in cities and industrial areas had to be much greater than that.

In addition to pollutants, snow preserves a small sample of air and water as well. Concentrations of carbon dioxide and other naturally occurring gases may be evaluated at various times to chart their variations in polar air. Oxygen and other stable (nonradioactive)

elemental isotopes can also effectively serve as thermometers for the whole Earth. When water is tied up in ice, less is available to ocean water, and the ratio of oxygen isotopes changes as a result. Carbon isotopes may also reflect the amount of biomass present on the planet. Studies of these stable isotopes have been used to evaluate the content of greenhouse gases in the atmosphere and to show the natural variations in the atmosphere. These data can be compared with current conditions to evaluate anthropogenic influence on

atmospheric chemistry and global warming. Ice core data are among the strongest evidence that humans are increasing greenhouse gases and causing global warming.

**global warming** At the time of the Industrial Revolution (around 1800), the amount of carbon dioxide (CO<sub>2</sub>) in the Earth's atmosphere was about 280 parts per million (ppm). In 2010, atmospheric CO<sub>2</sub> levels were 390 ppm and rising at a rate of 2 ppm per year. Because CO<sub>2</sub> is very effective at capturing

the infrared radiation given off by the Earth's surface after it has been heated by the Sun, the more CO<sub>2</sub> in the atmosphere, the warmer the planet becomes. This process, called global warming, can lead to climate change with major changes in long-term planetary temperatures, precipitation (rainfall) patterns, and even ocean levels. When first observed by atmospheric scientists in the 1950s, the increase in CO<sub>2</sub> levels was thought to be part of the natural variation in the Earth's atmospheric composition that had been taking place for many millions of years. However, the steep increase in CO<sub>2</sub> concentrations (almost 40 percent in 200 years) was much higher than any previously thought to have occurred and appeared to be directly linked to the massive, worldwide burning of fossil fuels that took place during this period. The eight warmest years on record (since 1850) have all occurred since 1998, with the warmest year (so far) 2005. Today, there are few mainstream scientists who

believe the rapidly increasing CO<sub>2</sub> levels in the atmosphere are not anthropogenic (caused by people's activities). However, there is still much uncertainty as to what the impact of a 485-ppm CO<sub>2</sub> atmosphere (anticipated by 2050) will be on human civilization.

Global warming has become the environmental issue that will drive human economic and cultural development for at least the next century. Addressing the issues surrounding this potentially devastating and catastrophic phenomenon has become so popular that the former U.S. vice president Al Gore was awarded the Nobel Prize in 2007 for helping to popularize and draw attention to the problem. He also won an Academy Award the year before for his documentary *An Inconvenient Truth*, an acclaimed and commercially popular documentary that called worldwide attention to ways pending climate change may impact both the United States and other countries around the world. There was even an international rock concert tour in 2007 to highlight threats to human health and the environment from global warming.

There are a small number of politicians and even a smaller number of scientists who vehemently deny global warming is occurring or claim that it is not anthropogenic. They rely on the insignificant scale (smallness) of human activity relative to the size and resiliency of the Earth and are resistant to accepting any connection between the use of fossil fuels and climate change. They see no reason or need to alter the cultural lifestyle of the United States or the rest of the world. As adamant as the global warming proponents, they claim that the climate of the Earth changes all of the time and has since the Earth was formed. However, this view is becoming more and more difficult to sustain in light of the increasing scientific evidence confirming that CO<sub>2</sub>-driven global warming/climate change is occurring. The United Nations, European Union, United States Environmental Protection Agency, National Academies of Sciences, as well as almost every major scientific and research organization in the world have published position statements that confirm CO<sub>2</sub> in the atmosphere is increasing because of fossil fuel usage and

Low-lying areas such as Funafuti Island—capital city of the South Pacific nation of Tuvalu—are particularly susceptible to damage from rising sea levels. (Ashley Cooper/Alamy)

### COMPARISON OF EARLY EARTH AND TODAY'S EARTH ATMOSPHERES

Early Earth Atmosphere (between 4 billion and 2.5 billion years ago)	Today's Atmosphere
H <sub>2</sub> O or water vapor: 80–85 percent	N <sub>2</sub> or nitrogen gas: 78.1 percent
CO <sub>2</sub> or carbon dioxide: 10–15 percent	O <sub>2</sub> or oxygen: 21 percent
CO or carbon monoxide	Ar or argon: 0.9 percent
N <sub>2</sub> or nitrogen gas	CO <sub>2</sub> or carbon dioxide: 0.04 percent
H or hydrogen gas	Other gases: less than 1 percent

that those increases are resulting, or will result, in changes to the Earth's climate.

#### CLIMATE HISTORY OF THE EARTH

Before the current period of global warming can be examined in context, normal climate variations must be defined. The climate of the Earth has varied greatly throughout its history. When the Earth was formed some 4.6 billion years ago, it had no atmosphere as known today. There are indications that there may have been light elements in an atmosphere, but they are speculated to have been removed by the solar wind. The surface of the Earth was so hot from the collisions of asteroids and meteorites that parts of the surface may have been molten rock. The great heat resulted in numerous volcanoes that released gases from the Earth's interior in a process called degassing. Gases that were released from molten rock and debris combined to form the early atmosphere. As the gases cooled and condensed, they rained down liquids that accumulated to form the early oceans.

The early atmosphere was still very warm and chemically very different from the current atmosphere. There was no free oxygen. Rocks of this age have minerals that would have been oxidized at the surface under current conditions, but they are not. The early atmosphere was rich in water vapor and carbon dioxide, which are strong greenhouse gases and certainly contributed to the high surface temperature present at this time in the planet's development.

The first major adjustment in the climate dynamics occurred with the development of photosynthetic cyanobacteria. Beginning around 3 billion years ago, in order to store energy, these primitive bacteria drove a chemical reaction to produce simple sugars as follows:

Although the main point of the process was to store energy in the sugars, the by-product of oxygen in the process had far greater implications for the atmosphere. These implications, however, were a long time in coming, because the free oxygen quickly reacted with one or more of the oxygen-poor compounds in the atmosphere and was removed.

The cyanobacteria, known as stromatolites, colonized the shallow oceans at the shorelines and proliferated about 2.5–3.0 billion years ago. They were so efficient at converting CO<sub>2</sub> into oxygen that by 2.2 billion years ago materials on the surface of the Earth began to oxidize (rust), and “red bed” sequences of rocks began to form. The reduction of CO<sub>2</sub> and other greenhouse gases in the atmosphere cooled the climate, and the first glacial deposits were formed. Since then, the climate has varied. It has mostly been warmer than it is now, but there have been relatively short-duration glacial periods scattered within it. At about 1 billion years ago, the Earth went into an “icehouse” mode, when the entire Earth became cold. Glacial deposits are interpreted to have formed even at very low latitudes. Most of the time after that, the Earth was primarily in a “greenhouse” mode, when there was no ice on the planet at all. Why the Earth shifts back and forth between greenhouse and icehouse modes is not fully understood.

There were major changes in the Earth's atmosphere over the past 500 million years. For example, the largest shift was about 250 million years ago, when plants colonized the land. For many millions of years, there were insufficient numbers of animals or efficiency of the animals to consume the vast amount of vegetation that was being produced. As a result, huge swamps developed, and most of the world's coal supply was produced at this time. Huge amounts of carbon were sequestered in the Earth, and the oxygen supply increased in the atmosphere. Within 25–50 million years, ice ages began again,

but vegetation was no longer being sequestered, as reptiles and dinosaurs evolved to consume it. The ice ages were similar to those of today in extent and duration, but conditions returned to warm and ice-free within a few million years.

About 65 million years ago, a large asteroid collided with the Earth. The evidence for it are an iridium-rich layer at the applicable time and abundant shocked quartz in sediments on a worldwide basis. A crater, named Chicxulub, which appears to be the point of impact, has been identified in the Gulf of Mexico. This collision is credited with having caused the extinction of the dinosaurs along with at least 75 percent of all land-dwelling species on Earth. Some of the most respected scientists at the time the theory was presented proposed that so much dust was emitted into the atmosphere that the Sun was masked for upward of one year. They proposed that it was equivalent to a nuclear winter. Other scientists hypothesized that this impact caused all of the vegetation on the planet to be consumed in a conflagration and cite carbon and oxygen isotope ratios in sediments of that age to prove their point. The problem with these doomsday scenarios is that many modern-day species such as mammals, birds, and frogs survived the event, and doing so would have been difficult if no food was available. This leaves the nature and extent of the damage from this collision in question.

After this period, the climate cooled dramatically as mammals became the dominant group. Rapid cooling separated long periods of stable climate over the next 30–40 million years. Oxygen ratios increased during this time, reaching their highest levels ever. About 4 million years ago, the climate again cooled into an icehouse mode. Since then, the climate has oscillated back and forth between ice ages and interglacial periods. We are currently considered to be in an interglacial period.

### **CAUSES OF GLOBAL WARMING**

There is a complex interplay of many factors that controls the temperature of the planet. Some of these factors are external, whereas others are internal to the atmosphere. The external factors have more control of the climate by far; internal factors are also important within their limitations. These factors are described as follows:

#### **Solar Radiation**

Although it appears that energy from the Sun is a constant, it is not. Evidence of the variability of the Sun includes sunspot activity and solar storms,

and scientists have even measured solar output for a short time. These variations of solar output show a cyclicity with time, suggesting that they may be part of a larger system of cycles. There even appear to be cycles in the total radiation output of the Sun, as well, though measurements show only small changes. No matter how important the other factors appear in climatology, they are surely dwarfed by the variability of solar output. This factor cannot be completely evaluated with our short period of observational data, but certainly with features like the channels of Mars on an otherwise frozen planet, the possibility of significant changes is not out of the question.

#### **Orbital Changes of the Earth**

The second most important factor in the temperature of the Earth is its distance from the Sun. This is another measure that would appear to be constant, but it changes on even a yearly basis. During the Earth's orbit around the Sun, it has a closest point called the perihelion that occurs on January 3 and a farthest point called the aphelion that occurs on July 4. This is an annual cycle for the orbit. There are other longer-term cycles in the Earth's orbit, as well, with no other outside influence. Scientists have identified a 100,000-year cycle and possibly several others. Add the gravity of other planets that may be closer and farther from the Earth to the equation, and the orbit could vary even more. These changes could be cyclical, as well, or they could be catastrophic.

#### **Tilt of the Earth**

At this point, the rotational axis of the Earth is inclined about 23.5° from the plane of its orbit around the Sun. It is this tilt that gives the Earth seasons. Solar heating of the Earth's surface is strongest when the incident rays of the sun are at 90°. The more gentle the angle of incidence, the less concentrated the radiation will be and the cooler the Earth. That is why the poles are cool and the equator is hot. During the summer solstice on June 21, the Sun rays strike the Earth directly (90°) along the tropic of Cancer at 23.5° north latitude. This is the most northerly point that the Sun rays strike directly during the year. At this point, the Northern Hemisphere is being heated more and is experiencing the warm weather of summer. Six months later, the Earth has moved in its orbit to the opposite side of the Sun and the direct rays strike 23.5° south latitude along the tropic of Capricorn. This is the farthest point south that there is direct radiation. It is the winter solstice and it occurs on December 21. The Southern Hemi-

**Position and tilt of the Earth relative to the Sun for the first day of each season. The yellow arrows show the orbit of the Earth around the Sun, and the red arrows show rotation of the Earth.**

sphere is heated at this time, leaving the Northern Hemisphere to experience the cold weather of winter. During the vernal and autumnal equinoxes on March 23 and September 23, respectively, the direct rays of the Sun strike the equator. That is the hottest place on the planet, as the Northern and Southern Hemispheres have moderating temperatures.

The rotation axis of the Earth, or North Pole, does not remain fixed. It shifts positions in cycles just as the other astronomical variations do. It has a short-term shift in circles that is like a wobbling top in which the Pole remains at 23.5° but points toward different places in the sky in a big circle, shifting from the North Star as the rotation axis. This procession of the axis is a 1,000-year cycle but may have little effect on climate. The Markowitz wobble is a very small angular cycle of shifting position of the pole with a period of about 30 years. Even larger shifts are possible but are probably very slow at about 1° per million years. There is evidence that there were much larger and quicker shifts in the past. If the shift causes the tilt angle to decrease, the effect of seasons will be reduced. The poles will become much colder and glaciers will extend much farther south. If the shift causes the tilt angle to increase, the direct incident rays of the Sun will cover a much larger area throughout the year, and the heat energy will be more evenly distributed. This would tend to reduce the amount of ice at the poles.

### Aerosols in the Atmosphere

Incoming sunlight must be able to reach the ground and be absorbed to heat up the atmosphere. Dust particles and liquid aerosols tend to reflect or disperse the incoming sunlight back into space. The more aerosols and dust particles, the less the Earth will heat. The best example of the power of aerosols in the atmosphere is the Indonesian volcano Tambora. In 1815, Tambora produced a large eruption with about 36 cubic miles (150 km<sup>3</sup>) of ejecta. Much of the ejecta were in the form of fine dust, which was shot high into the atmosphere and spread around the world. This fine dust reflected a portion of the incoming solar radiation back into space, thus reducing the heating of the Earth. As a result, 1816 was referred to as the "year without a summer." Snow fell in New England through the month of June, and, as a result of the cold, there was a worldwide famine. The effect ended within a few years and only 1816 had drastic changes. Tambora, however, was small in comparison to many other volcanoes. The Indonesian volcano Toba, for example, erupted 74,000 years ago and emitted 700 cubic miles (2,800 km<sup>3</sup>) of ejecta. This was well before historical records, so we do not know what effect it had on the weather. There have been many other prehistorical eruptions as large as Toba, which could have drastically altered climate.

Another great potential source of reflecting dust in the atmosphere is an extraterrestrial impact. It

is hypothesized that when the asteroid that potentially caused the extinction of the dinosaurs struck the Earth 65 million years ago, it caused a “nuclear winter.” In this scenario, so much dust is raised into the atmosphere that it reflects back a large percentage of the incoming solar radiation, keeps the whole world in darkness, and drops temperatures to winter conditions throughout the planet. This condition is hypothesized to be intense for one year, and effects could last a decade or more. This is an extreme situation that happens so infrequently that it is typically not factored into any climate models.

Human activities not only lead to an increase in carbon dioxide in the atmosphere, but also produce an enormous amount of particulate matter. Some scientists are now finding that the rapid melting of glaciers may be the result of particulate covering them and absorbing solar radiation rather than reflecting it, as ice should. Global warming may be a minor effect. This particulate has spread throughout the troposphere and even into the stratosphere. Particulate and aerosols, which have also greatly increased through human activities, reflect the sun-

light back into space. They, therefore, cause global cooling.

The term *nuclear winter* was coined to describe what would happen if there were a nuclear war. Nuclear war would have the capacity to alter the climate greatly. In addition to the many other catastrophic changes to the environment that would ensue from a nuclear war, the explosions would raise enough particulate into the atmosphere that solar radiation would be inhibited at the surface because it would be dispersed and reflected. As a result, it would be dark and very cold on a planetary scale. This scenario is probably moot because there would be few, if any, humans left to witness it.

### Surface Albedo

Several years ago, a major airline conducted a study and found that they could save a significant amount of money in cooling costs by painting the tops of their airplanes white. While waiting to take off, airplanes get very hot sitting on the tarmac. They need to expend fuel needed for flying to run the air-conditioning. Painting the top of the plane white caused

Graphs of changes in carbon dioxide (A) and temperature (B) with time from 1880 to 2000. Measurements of global carbon dioxide from 1880 to 1960 are from trapped gas in ice cores, whereas after 1960 they are measured at Mauna Loa, Hawaii, and show seasonal variations. Temperatures are shown in deviation from average over the recording period and are also from Mauna Loa.

the incoming solar radiation to be reflected away. This is the same reason why white cars are cooler than black cars. The variable that measures reflectivity is called surface albedo. The surface albedo of the Earth varies depending upon the location. In most wooded areas, solar radiation is strongly absorbed, whereas in glacial areas it is reflected. Normally, it is desirable for solar radiation to be absorbed because it can be converted into stored energy by vegetation through photosynthesis. In global warming terms, it is not desirable because more heat is held in the atmosphere. Snow and ice are undesirable because they simply reflect back the energy and do not store it for human or animal consumption. In global warming terms, snow and ice reduce absorption of heat and thereby reduce global warming. This presents a dangerous positive feedback mechanism for global warming. As the temperature climbs, the glacial ice melts and retreats, leaving more surfaces to absorb rather than reflect solar radiation. The newly exposed surface absorbs the solar radiation, thereby heating up the atmosphere and melting more ice and snow.

### Mountain Ranges

The number and distribution of high mountain ranges can also have an effect on climate. High and extensive ranges can divert wind and weather systems to some extent. They can force colder air toward lower latitudes and warmer air toward the Poles. Pulling warm air into colder regions can result in overall warming. Another effect of mountains is to raise the elevation of the surface to where it can support snow cover. The presence of snow cover at lower latitudes reflects back solar radiation that would have been used to heat the planet at normal elevations.

### Ocean Changes

Although it may not be readily apparent, the global climate is strongly influenced by both sea level and ocean circulation. Ocean currents play an integral role in distributing heat around the planet. They moderate coastal and even regional temperatures and precipitation. A good example is the Gulf Stream in the Atlantic Ocean. It keeps the British Isles and most of Western Europe temperate and habitable even though they are at the same latitude as Labrador, Canada, on the other side of the Atlantic Ocean, which is prohibitively cold. In reality, this effect of temperature distribution through ocean circulation is even more profound on the global scale. It is, therefore, essential to have good circulation to keep the temperature moderated. In geologic history, when ocean circulation was reduced, the Poles were much colder and promoted quick global cooling.

This restriction in ocean circulation occurred not only through obstruction by landmasses but also by glacial ice. Not only does the ice freeze the surface of the ocean, it also lowers sea level by the amount of water consumed in producing the glaciers both on land and in the sea. Lower sea level reduces circulation and ocean influence on climate. This is one of the main reasons (in addition to surface albedo and others) that when an ice age begins, it develops very quickly. Scientists describe it as a switch: The ice age is on or it is off; there is no in between.

There are other factors in sea level and ocean circulation as well. These are mainly tectonic in nature. Inflation and deflation of the midocean ridges can cause sea level to vary. During the Paleozoic, from about 500 million years ago to 220 million years ago, the sea level was mainly much higher than it is today because of inflation of the ridges, thus displacing the ocean water. The entire central part of the United States was under a shallow ocean for periods of tens of millions of years at a time. There was much more water in the atmosphere at the time, and circulation of surface waters was greatly enhanced. The ocean basins were shallower as a result of this inflation, and deep circulation was subdued. The Earth was warmer as a result.

### Living Organisms

Although, in most cases, living organisms as populations change too slowly to have an appreciable effect on the atmosphere, radical changes in populations or evolutionary advances can have great effects. Carbon dioxide is removed from the atmosphere and oxygen returned by the photosynthetic activities of plants and bacteria. Any disruption of the plant population by an ice age, asteroid impact, or even global deforestation in productive areas such as rain forests could reduce global photosynthesis and result in excess carbon dioxide. By the same token, any increase in population or evolutionary advances in the photosynthetic capacity of these organisms could increase the amount of oxygen in the atmosphere.

The other organisms that exert control on the composition of the atmosphere are shell-producing organisms in the ocean. The ocean is a huge sink for carbon dioxide as well as other atmospheric gases, and there is a constant exchange. The carbon dioxide in the ocean is used by certain organisms to build shells. The most abundant of these organisms are plankton, algae, and corals. Pollution of the ocean, destruction of habitat, and destruction of reefs by humans have taken their toll on these beneficial organisms. Without them, there would be a surplus of carbon dioxide in the oceans and consequently in the atmosphere as well.

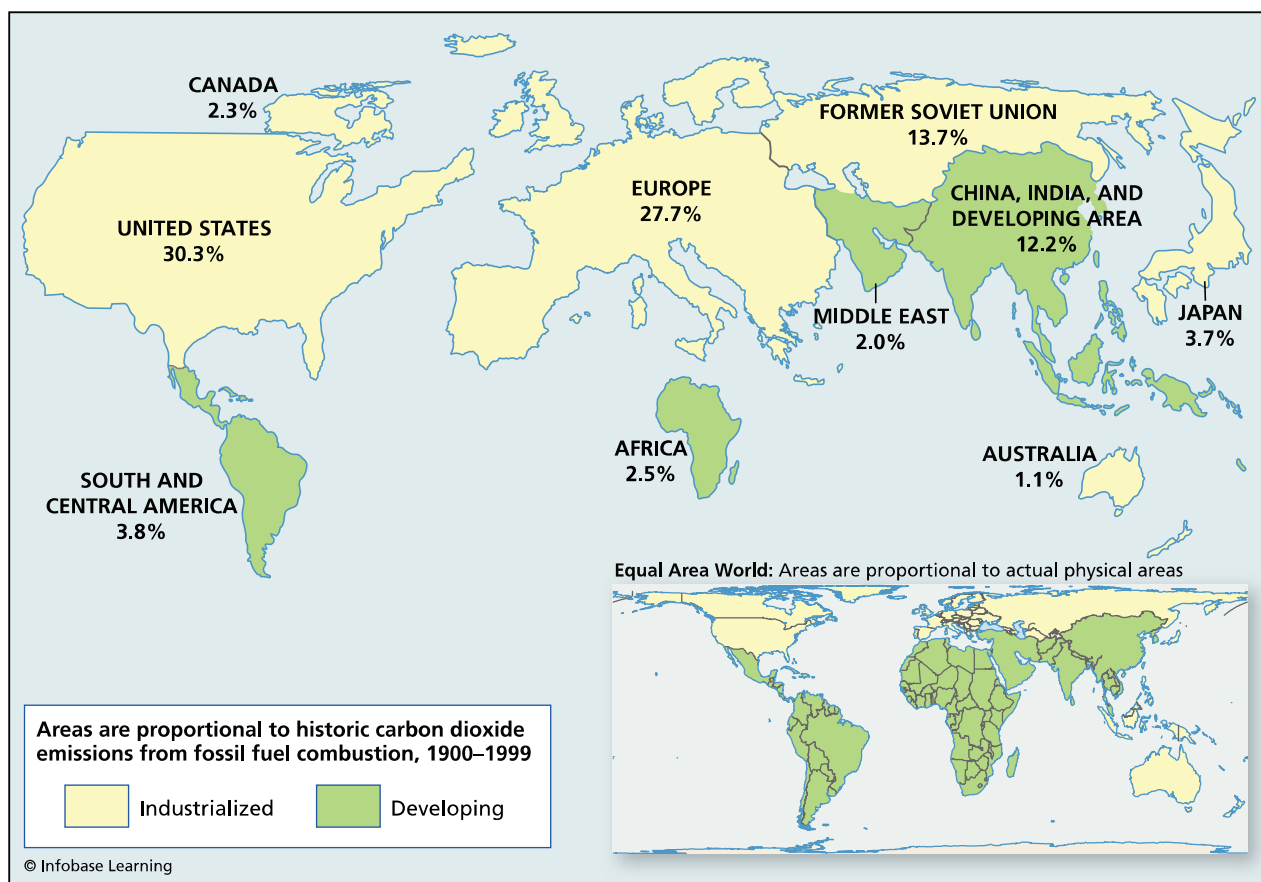

### THE GREENHOUSE EFFECT

The greenhouse effect occurs when solar radiation that enters the atmosphere cannot escape and thus heats it up as in a greenhouse. The reasons that the solar radiation is trapped are several. Incoming solar radiation has a short wavelength and can penetrate all of the gases in the atmosphere. When it is absorbed by the surface, it is converted into long-wavelength radiation or heat. Gases such as oxygen allow the shortwave radiation to pass in and the long-wave radiation to pass back out of the atmosphere again. Certain gases, carbon dioxide, for example, do not allow all of the long-wave radiation to pass back out but instead absorb it. The absorption heats the atmosphere and causes global warming. Carbon dioxide is, therefore, called a greenhouse gas. It is the gas of most concern because it is increasing so fast. In fact, there are much stronger greenhouse gases than carbon dioxide. Methane, for example, which is also increasing dramatically as the result of human activity, is 23 times stronger a greenhouse

gas than carbon dioxide. The amount of anthropogenic methane released to the atmosphere, however, is far less than the amount of carbon dioxide. Other greenhouse gases include nitrogen oxides, chloro-fluorocarbon (CFC) propellants, vapors of numerous organic compounds, and even water vapor.

Anthropogenic carbon dioxide is added to the atmosphere at a rate of an estimated 3.5 million tons (3.2 billion metric tons) annually. Energy-related carbon dioxide emissions, resulting from petroleum and natural gas, represent 82 percent of total U.S. industrial greenhouse gas emissions. This is the reason that all of the focus of the global warming debate has been on carbon dioxide. The question of how we can determine which carbon dioxide is anthropogenic and which is from respiration or other natural sources was answered in the 1950s by Hans Suess. He found that natural carbon dioxide included radiogenic carbon, whereas carbon dioxide from fossil fuels does not. The reason is that radiogenic carbon is produced in the atmosphere

**Schematic map of the world with size of areas (countries or continents) reflecting their average production of carbon dioxide through the 20th century. The numbers on the areas reflect their percentage of the total world production. The inset map shows the areas in their actual sizes.**

and all natural carbon dioxide contains it. Once the carbon is removed from the atmosphere, it decays to a more stable form and the remaining carbon is “dead.” It was the work of Suess and Roger Revelle that led to the recognition of the greenhouse effect. As a result, Revelle has been widely acknowledged as the “grandfather of the greenhouse effect” by most of the current proponents of the theory, including Al Gore. In his book and Academy Award-winning documentary *An Inconvenient Truth*, Gore applauds Revelle for his efforts.

There is no question that carbon dioxide in the atmosphere increased radically in the late 20th century and continues to do so in the 21st century. In his documentary *An Inconvenient Truth*, Al Gore highlights the radical increase from the previous levels and refers to it as the “hockey stick” in the graph. Even though the percentage of carbon dioxide in the atmosphere is still very small, at 0.0384 percent, or 384 parts per million (ppm), this is an increase of 100 ppm from preindustrial times, or an increase of 35 percent. About 20 percent of this 35 percent has occurred since 1960. The questions still in debate are whether this increase in carbon dioxide in the atmosphere is anomalous and whether it is the sole culprit in the current global warming cycle.

### ESTABLISHING A NATURAL VARIATION BASELINE

In order to answer the question of whether these increases in temperature and carbon dioxide levels are really anomalous relative to normal atmospheric variations, scientists must establish what normal is. Federal agencies that fund basic research on the climate and atmosphere have invested heavily to determine these natural variations. The most common research involves drilling ice cores into the Greenland and Antarctic ice sheets and analyzing them. When the snow fell that would be compressed into ice, it trapped some air. The composition of that air contains information on both the carbon dioxide concentrations at the time as well as the temperature that can be obtained by using oxygen isotopes. These cores yield detailed information on carbon dioxide level in the atmosphere for the past 100,000 years or more. The temperature information, however, is only at the Poles and may not reflect changes at the middle latitudes. Global warming cannot be correlated with carbon dioxide without additional data.

Climate data for the middle latitudes are not readily available because the surface is constantly reworked at the oceans. Lakes yield a much more continuous and undisturbed record of the climate

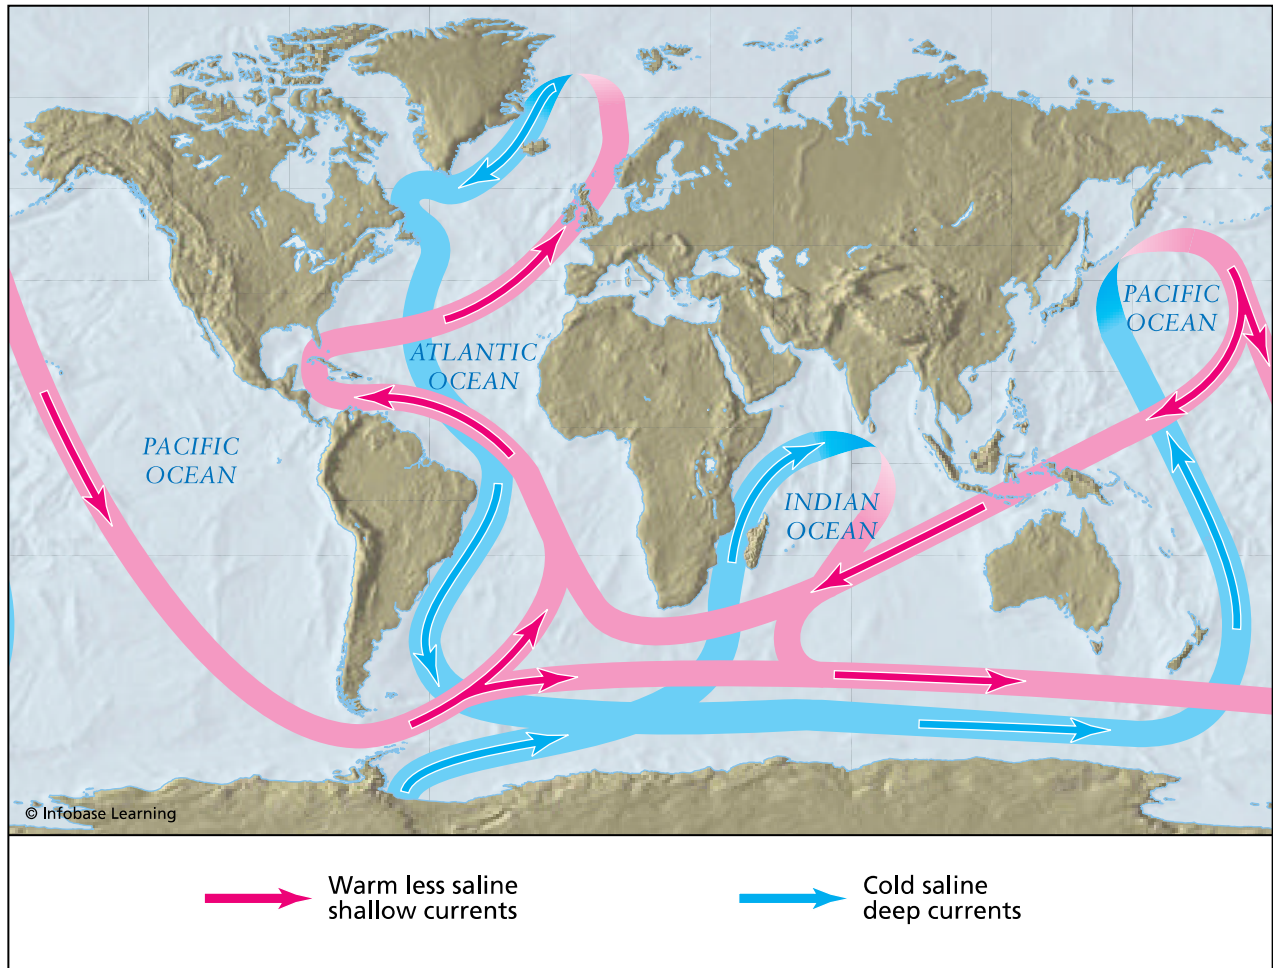

than oceans. The first real study of climate variations over extended periods was conducted on the Newark Basin in New Jersey. The Newark Basin was deposited between 200 and 225 million years ago when the Atlantic Ocean opened: It formed in a large rift valley that contained very large lakes. Depending upon climate, the water level of the lakes varied, and lakes even dried up in extended periods of dry climate. These rocks are probably the longest continuous sequence of nonmarine deposition in the world. The idea was that they could indicate the natural variations in the Earth's climate over a long period.

A continuous core of rock was drilled completely through the rocks of the Newark Basin and studied. The analysis included chemistry, physical character, fossils, magnetism, and several other pieces of data that were all integrated to show the variations in lake levels, sedimentation rate, vegetation, and other quantities that reflect climate variations. Using a polynomial fitting and analysis of the climate graphs that were produced, several orders of climate change cycles were identified. Many of these cycles are astronomical in origin and are called Milankovitch cycles after a famous mathematician who studied cyclical functions. Others reflected changes in sea level, ocean circulation, and other internal variations. This study became the first extensive baseline for climate variability in the midlatitudes.

More recently, cores have been and are being drilled in the deep lakes of the east African Rift system. Although drilling a continuous core of sediment and retrieving it from the rugged and poorly accessible Lake Tanganyika and Lake Malawi are difficult, the information will be even more useful. The problem with the Newark Basin data is that they could not be correlated with the ice core data. These new analyses will give us a much better picture of whole-Earth changes in climate.

### CURRENT EFFORTS TO REDUCE GLOBAL WARMING

There have been numerous local and several worldwide attempts to reduce carbon dioxide as well as several other air pollutants. The first international congress to address global environmental issues was the 1972 United Nations (UN) Conference on the Human Environment in Stockholm, Sweden. It was a breakthrough at the time that environmental issues could even be considered by an international group of such stature. Many issues were discussed at the conference, including greenhouse gases and global warming, but little was accomplished in the ensuing

**Map of the Earth showing the distribution of deep cold ocean currents (blue) and shallow warm ocean currents (pink). Locations where they change from blue to pink indicate upwelling, and where they change from pink to blue, surface water is sinking.**

years and conditions worsened considerably. Concern over this continuing environmental degradation led the UN General Assembly to convene the 1983 World Commission on Environment and Development. The report of this commission (known as the Brundtland Report) was a catalyst for the 1992 UN Conference on Environment and Development (UNCCD).

The UNCCD, or Earth Summit, was held on June 3 and 4, 1992, in Rio de Janeiro, Brazil. The conferees of the Earth Summit agreed on a global blueprint for sustainable development called Agenda 21 and on two sets of principles, the Rio Declaration on Environment and Development and the Forest Principles. This agenda included a multinational pledge to reduce emissions of greenhouse gases to 1990 levels by the year 2000. The idea was that developed nations, which produce three-fourths of the world's pollution, would investigate and develop new technology to reduce or reverse global warm-

ing. The beginnings of the Intergovernmental Panel on Climate Change (IPCC) were also a result of this conference. The problem was that negotiations with individual nations on central issues, such as population, energy, forest production, and consumption, made Agenda 21 relatively ineffective.

After the eventual success of the 1987 Montreal Protocol by the mid-1990s to reduce CFCs and protect the ozone layer, environmentalists attempted to gain a similar agreement with the Kyoto Protocol. To do this, the United Nations held a conference in Kyoto, Japan, in December 1997 and forged a document. The Kyoto Agreement, Treaty and Protocol is a program designed to reduce the total global emission of six greenhouse gases—carbon dioxide, methane, nitrous oxide, sulfur hexafluoride, hydrofluorocarbons, and perfluorocarbons—averaged over the period of 2008–12 by 5.2 percent relative to 1990 levels. Limitations for individual countries range from 8 percent reductions for the European

Union and some others to 7 percent for the United States, 6 percent for Japan, 0 percent for Russia, and permitted increases of 8 percent for Australia and 10 percent for Iceland to induce them to ratify it. The initial agreement was signed between March 16, 1998, and March 15, 1999, but efforts to achieve complete world participation continue. As of June 2008, 182 parties had ratified the protocol, including 137 developing countries. The only major industrialized country that did not ratify the agreement was the United States because it was strongly opposed by the Bush administration. President Obama worked to have the agreement ratified by the United States when he took office.

One problem is that India and China, which are the most populous countries in the world and increasingly producing greenhouse gases, are not required to reduce hydrocarbon emissions but instead need only to monitor and report emissions. Both have ratified the agreement, as has Brazil, which is under the same constraints.

There is much confusion over what constitutes a real effort in curbing greenhouse gases, and true progress is slow to nonexistent. Even Al Gore's documentary *An Inconvenient Truth* has led to some confusion. He developed an idea about carbon exchange units and proposed essentially that planting a tree could offset hydrocarbon usage. In reality, a tree only temporarily sequesters carbon. If the tree is burned in a fireplace or allowed to rot on the surface, the vast majority of the carbon returns to the atmosphere. The only way to reduce carbon dioxide emissions is to reduce consumption of fossil fuels drastically. Indirect reductions such as the elimination of ocean pollution will also help. The situation, however, is quite dire.

#### Gore, Al Albert Arnold Gore, Jr. (1948– ) American Politician, Environmental Spokesperson

Al Gore is one of the most prominent and controversial personalities in American politics and popular culture from the late 1980s to the present. Although he started out as a rather generic young politician, Gore made a decision to become an environmentalist, and, as a result, he has become the most effective spokesperson for the battle against global warming in the world. He did not initially focus so strongly on global warming; he first took up the efforts of Rachel Carson and battled chemical pollution and toxic waste, citing Carson as his inspiration. He was even called "Ozone Man" for his focus on the problems of chlorofluorocarbons (CFCs) and stratospheric ozone reduction. As an undergraduate student, however, he crossed paths with Roger Revelle at Harvard University, who is considered "the grandfather of global warming." Gore credits Revelle for introducing him to the problem with such passion that Gore has decided to take up the battle on more fronts and with more effectiveness than Revelle would have ever dreamed possible.

#### BIOGRAPHICAL INFORMATION

Albert Arnold "Al" Gore, Jr., was born on March 31, 1948, in Washington, D.C., the son of a U.S. congressman from Tennessee. Al Gore split his time between a farm in Carthage, Tennessee, in summers and in Washington, D.C., during the school year. He attended the exclusive St. Alban's Episcopal School for Boys and graduated in 1965. That fall he enrolled in Harvard University, where he was the roommate of the actor Tommy Lee Jones. Gore graduated in 1969 with a bachelor of arts degree in government with honors. He also married Mary Elizabeth "Tipper" Aitcheson that year. Although he could have avoided military service and was opposed to the Vietnam War, Gore chose to enlist in the U.S. Army on August 7, 1969, to fulfill his civic duty. He was sent to Vietnam on January 2, 1971, to serve for

**Al Gore speaks at the Grenelle de l'Environnement ecological talk at the Élysée Palace in Paris, France, October 2007**  
(Philippe Wojazer/Reuters/Landov)

five months as a field reporter. He returned to the United States in 1971 to enroll in divinity school at Vanderbilt University. He also accepted a position as a reporter for the *Tennessean*, the local Nashville newspaper. In 1974, Gore enrolled in law school at Vanderbilt University.

Al Gore's political career began in 1976, when U.S. Congressman Joe Evins announced his retirement after 30 years. Gore quit law school and, after winning the Democratic primary, ran unopposed for Tennessee's fourth district seat. He would later win reelection in 1978, 1980, and 1982. In 1984, Gore would win election as U.S. senator, succeeding Howard Baker. Al Gore ran for president in 1988 but finished second to Michael Dukakis in the Democratic primaries. In 1992, Bill Clinton chose Gore as his running mate, and they were elected and then reelected in 1996. Al Gore served as the 45th vice president of the United States from 1993 to 2001. Gore was the Democratic nominee for the presidency in the 2000 election and won the popular vote but was defeated in the electoral vote and lost

the most hotly contested election in recent history. Since then, Gore has served as visiting professor at Columbia University, the University of California at Los Angeles, and Middle Tennessee State University. He has also been involved with several investment companies and several business ventures. Gore continues to write books and even made a documentary on global warming. Although Al Gore decided not to run for president in 2008, it is unlikely that his career in public service, and as an advocate for the environment, is over.

### ENVIRONMENTALIST

Al Gore claims that his interest in environmentalism began at a young age. When Rachel Carson's book *Silent Spring* was published in 1962, it became a major topic of conversation in the Gore household. Although he was a supporter and instigator of efforts to protect the environment during his years as congressman and senator, Al Gore's real birth as an environmental spokesperson occurred in 1989, when

he wrote the environmental book *Earth in the Balance*. It was the first book written by a current U.S. senator to make the *New York Times* Best Seller List since John F. Kennedy wrote *Profiles in Courage* more than 30 years earlier. The book supported the entire environmental movement but especially the idea of greenhouse gases and global warming.

Al Gore was involved in several environmental efforts as vice president. In 1994, he helped launch the GLOBE project, a worldwide environmental-educational initiative that utilized the Internet, Gore's other major area of interest and fame. Gore strongly supported passage of the Kyoto Treaty of 1997, which established restrictions on carbon dioxide output. Although this project should have been a great victory, the U.S. Congress refused to enact it, leaving Gore open to criticism by environmental supporters, ultimately hurting him politically.

Al Gore has probably been a more effective environmental advocate and spokesperson since he left the vice presidency. These efforts culminated in the production of the documentary film and accompanying book *An Inconvenient Truth* in 2006. The theme of the work is the global climate change crisis and potential methods to combat it. The film won the 2007 Oscar (Academy Award) for a documentary feature and the 2007 Sir David Attenborough Award for Excellence in Nature Filmmaking at the Santa Barbara International Film Festival, among others. To date, it has become the documentary with the third-highest box office gross sales. The book has also made the best-seller list. Gore and his associates have crossed the country presenting the warnings of global warming to literally hundreds of audiences. He even addressed Congress as a private citizen. He helped organize the Virgin Earth Challenge, which provides a prize of \$25 million to any group or individual to present a viable way to remove greenhouse gases from the atmosphere, as well as the worldwide Live Aid Concerts on July 7, 2007, to help battle global warming.

Gore initiated several business ventures that encourage the reduction of greenhouse gases. He has been a great proponent of quantifying the carbon footprint of humans from the country to the individual level. The idea of carbon offset or exchange is that if people contribute carbon dioxide to the atmosphere, then they should plant a tree or do other things, such as drive an electric vehicle, to reduce an equivalent amount. This idea promotes environmental sustainability, though the global warming situation is nowhere near sustainability at this point. As a result of all of these efforts to call global warming to the attention of the public, Al Gore won the Nobel Prize in peace in 2007.

**Greenpeace** The image that the name Greenpeace calls to mind is a small ship or boat manned by several activists and positioning itself in front of a much larger, more threatening vessel in order to prevent some action. Indeed, that is the image that Greenpeace hopes to project, and they have disrupted nuclear testing, whale hunts, and baby seal hunts with these nonviolent protests. Their mission statement is as follows:

Greenpeace is an independent, campaigning organization which uses peaceful direct action and creative communication to expose global environmental problems and to force solutions for a green peaceful future. Greenpeace's goal is to ensure the ability of the earth to nurture life in all of its diversity.

Greenpeace is the largest and one of the few successful organizations that are based on ideals of the radical 1960s. Greenpeace International now has an international membership of between 2.5 and 5 million people with an estimated \$360-million global empire and 27 national and regional offices in 42 countries. They have been labeled ecoactivists, ecoextremists, and ecoterrorists by supporters and detractors alike. Regardless of the political positioning and controversy that surround Greenpeace in virtually all of its efforts, it is made up of a large number of people who are truly concerned about the natural environment of the Earth and are willing to take action to protect it. Some activities of Greenpeace are certainly questionable, and their motivations have come into question, but, in general, Greenpeace has been one of the most effective organizations to protect the natural environment and provides great hope for continuing these actions in the future.

## THE HISTORY OF GREENPEACE

The Greenpeace organization began in 1969–70 in Vancouver, Canada, when a group of radical Americans from the antiwar group the Don't Make a Wave Committee (founded by James and Marie Bohlen) were joined by several Canadian activists in the basement of a Unitarian church to protest U.S. nuclear bomb testing. They planned to stop the test, code-named Cannikin, beneath Amchitka Island in the Aleutian Islands, Alaska, by putting themselves in harm's way in a small boat called the *Phyllis Cormack*. The U.S. Coast Guard scuttled the attempt, but it brought the core group together and galvanized their resolve. The *Phyllis Cormack* was called *Greenpeace I* by the members and a successor vessel was named *Greenpeace Too*. Early support was from the Quaker church, as several of the key members were in the Society of Friends and the group was aligned with the much better established Sierra Club prior to the trip to Amchitka. After that, the more radical Greenpeace organization grew ever further from the more conservative Sierra Club.

On May 4, 1972, the organization officially adopted the name *Greenpeace Foundation*. The yacht *Vega* was renamed the *Greenpeace III* that same year, and it participated in a protest against the testing of French nuclear devices in the atmosphere at Mururoa, French Polynesia, but was unsuccessful. The boat *La Flor* set out from Melbourne, Australia, to disrupt testing in 1974 and was dubbed *Greenpeace IV* but was also unsuccessful. That same year, the Vancouver-based group initiated their famous antiwhaling campaign and encountered whaling vessels from the Soviet Union off Mendocino, California. They had another encounter with the Soviet whaling fleet in 1976 in the ship *James Bay*, which was renamed *Greenpeace VII*, with much greater success as the result of better information and funding. It is the picture of a small boat full of angry protesters facing down a huge Soviet whaling boat that comes to mind for most people when they think of Greenpeace. The year 1976 was also historic for Greenpeace because they launched another high-profile campaign against the beating and killing of seal pups in Newfoundland just for their skins. The skins were used in the high-fashion garment industry, and the campaign received extensive publicity in the media, especially when Brigitte Bardot joined Greenpeace in the effort.

After the original Vancouver-based Greenpeace group encountered financial difficulties and disputes over operations, David McTaggart seized the opportunity to develop a new structure for the organization. After extensive lobbying efforts, on October 14, 1979, Greenpeace International unified the for-

merly independent Greenpeace offices under a single umbrella that would determine the overall direction of the organization. Although there was much criticism from both within and outside the organization that Greenpeace had become similar to the hierarchical organizations it was fighting, the new reorganization allowed initiatives to be much better orchestrated. Another big change in Greenpeace at this time was the purchase of the much larger fishing trawler *Sir William Hardy*, which was completely restored and refitted before being renamed the *Rainbow Warrior*. With this large vessel, Greenpeace could gain much more attention and be more effective in their efforts. The *Rainbow Warrior* was used extensively between 1978 and 1985 in non-violent direct action against ocean dumping of toxic materials and nuclear waste, the gray seal hunt in Orkney, and nuclear bomb testing in the Pacific region, among many others.

In 1985, the *Rainbow Warrior* returned to the Maruroa atoll where France tested its nuclear devices. While it was in a New Zealand harbor, France planted demolition devices on the boat and blew it up, sinking the *Rainbow Warrior* and killing a Dutch freelance photographer who was aboard. Although Greenpeace lost its famous ship, the publicity put the organization back in the limelight but this time as a victim of an unprovoked attack from an evil French government. It was a great boon to their image and rejuvenated their membership. As a result, France was forced to pay fines to New Zealand and the family of the photographer. It was also the last straw for New Zealand, which passed legislation in 1987 to declare itself a nuclear-free zone, thus making it very difficult for France to mount nuclear testing in the area.

Greenpeace commissioned a second *Rainbow Warrior*, in 1989, which remains active today. In 1996, the *MV Sirius*, another Greenpeace vessel, was detained by Dutch police but released soon afterward. Nonetheless, it again put Greenpeace back in the public eye. Other current ships include the *Arctic Sunrise*, *Esperanza*, *Witness*, and *Billy Greene*. Greenpeace has offices in Argentina, the Australia-Pacific region (Australia, Fiji, Papua New Guinea, Solomon Islands), Belgium, Brazil, Canada, Chile, China, Czech Republic, France, Germany, Greenpeace Nordic (Denmark, Finland, Norway, Sweden), Greece, Greenpeace Central and Eastern Europe (Austria, Hungary, Slovak Republic, Poland, Romania, Bulgaria, Slovenia, Serbia, Montenegro, and Bosnia, with no permanent campaign presence in the latter five states), India, Italy, Japan, Luxembourg, Greenpeace Mediterranean (Israel, Cyprus, Lebanon, Malta, Tunisia, Turkey), Mexico, the

Netherlands, Greenpeace Aotearoa New Zealand (New Zealand), Russia, Southeast Asia (Philippines, Indonesia, Thailand), Spain, Switzerland, the United Kingdom, and the United States.

### CURRENT ACTIVITIES

Greenpeace has priority areas where their efforts are concentrated. These priority areas are determined at the central headquarters in Amsterdam, the Netherlands, by vote of the regional offices and indeed the entire membership. There is never full agreement on all issues and some offices put more effort into some priorities than others. There are also local priorities that a particular office may emphasize but that may not be global priorities per se. The current priority areas are listed in the following.

#### Stop Global Warming

This effort is primarily one of petitioning legislative bodies and public education. The efforts are intended to persuade the U.S. Congress both to support legislation that would reduce greenhouse emissions and to switch oil subsidies to renewable forms of energy such as solar and wind technology through a letter-writing campaign. The other effort is to persuade people to stop purchasing automobiles that are not efficient, particularly sport utility vehicles (SUVs) and pickup trucks. Greenpeace uses its legal connections to try to force change through court cases to lobby elected officials. The lobbyists have made some headway but primarily in countries other than the United States. They made great efforts to gain support for the 1997 Kyoto Protocol and were instrumental in inducing many countries to ratify it.

#### Oceans

Greenpeace has traditionally emphasized and been most effective with issues related to the oceans. Efforts are still being made to eliminate whaling through direct action. Although Greenpeace has made significant headway in reducing whaling, some countries still engage in it. Most recently, Greenpeace confronted the Japanese whaling fleet and scuttled their attempts to take whales. They are also involved with the prevention of overfishing by the fishing industry and ocean dumping of both garbage and industrial waste. In addition to whaling and simply taking too many fish from the ocean, Greenpeace is actively opposed to factory fishing and large-scale industrial practices, bottom trawling that destroys coral reefs and takes potentially endangered species, by-catches of unintended fish and mammals, and ocean farming, which is apparently inefficient. Their work is both physically confrontational with

the fleet of ships and legislatively oppositional. They also have public educational campaigns to reduce plastic waste from the oceans simply by reducing litter and recycling.

#### Forests

All of the efforts that have gone into saving forests over the years have given environmentalists the nickname "tree huggers." Although in many areas there has actually been an increase in forestation over the past few decades, in many critical areas, deforestation continues unabated. Greenpeace is actively pursuing a program to stop deforestation in the tropical rain forest of the Amazon basin. They are raising a large sum of money to provide financial incentives as well as working with legislators to stop deforestation by 2015. The Greenpeace Jaguars, however, are a group of people on dirt bikes who roam the Argentine forests looking for bulldozers to menace. The rain forest effort is largely being orchestrated by the Brazil office. Another initiative is to have deforestation included in treaties such as the Kyoto Protocol to reduce greenhouse gases. Other areas of concerted efforts are Alaska forests, Indonesian forests, and a boycott of palm oil. It seems that in many areas, rain forests and especially peatlands are cleared to plant palm oil plantations. Both of these actions contribute to global warming.

#### Nuclear

Greenpeace's efforts regarding nuclear energy are on two fronts: reducing nuclear energy and disarmament. Greenpeace began attempting to block nuclear testing, and it is indeed a legacy of the organization that through several far-reaching treaties, nuclear testing is essentially nonexistent, although not completely banned. The more than 2,000 nuclear weapons tests that have already occurred have left global and regional contamination. Even with all of the dismantling of the nuclear arsenal in recent years, there are still nearly 36,000 nuclear weapons around the world with thousands on standby alert. There are 500 nuclear reactors aboard submarines. Many emerging countries such as Iran are attempting to develop nuclear capability as well. Greenpeace is actively attempting to influence legislators to reduce the nuclear arsenal. It is also fighting the operation and construction of nuclear power plants primarily because of the cost, the danger of an accident such as those at Chernobyl and Three Mile Island, and the potential targeting of nuclear power plants by terrorists. They are also using the disposal of high-level nuclear waste as a deterrent, though not as forcefully. Most of the efforts are in public education and attempts to influence legislators.

### Toxics

Greenpeace is addressing not only the overuse of toxic industrial chemicals, but also the location of chemical plants. Ever since 9/11, potential terrorist targets have been identified and evaluated for their vulnerability to attack, including chemical plants. The U.S. Environmental Protection Agency (EPA) has shown that the presence of more than 100 chemical plants in the United States threatens the safety of 1 million or more people in an area up to 25 miles (40 km) away from a plant. Further, the U.S. Naval Research Laboratory estimated that at least 100,000 people could be killed or injured in the first 30 minutes if any of these plants or even a train carrying chlorine gas or another toxin were successfully attacked by terrorists. Greenpeace has lobbied legislators to reduce this threat, with positive results. Greenpeace is also addressing the pollution problem posed by the disposal of old electronic devices (also known as e-waste). These devices primarily contain heavy metals and plastics, but some can contain dangerous organic fluids and even radioactive sources. The primary efforts to address the problems are in public education

and lobbying the electronics industry. They are encouraging Apple Inc. to be the green leader in this effort.

### Genetic Engineering

One of the latest efforts by Greenpeace is to fight the introduction of genetically engineered food (or “frankenfood,” as it has been called) into consumer products. They feel that genetically engineered (GE) food is not tested rigorously enough and, as such, could pose serious potential health threats of unknown proportions. Greenpeace was involved with the recall of the GE corn that mistakenly made its way into the market in 2006. The first step is to have companies label food that contains GE products. Even then, because livestock is fed GE grains, people are still being exposed to it.

**groundwater** When meteoric water precipitates from the clouds to Earth, it has several potential paths. It can simply become surface runoff and

flow to the nearest downhill stream in the drainage basin. It can also be stored on the surface as snow and ice or in a swamp or vernal pool or any number of biologic or anthropogenic sinks. Some water can simply evaporate and return to the atmosphere. None of these paths, however, directly contributes to the groundwater supply; only water that infiltrates the soil or rock forms subsurface water and groundwater.

Infiltrating water penetrates the surface and enters the vadose zone, which only contains water during precipitation, flooding, and melting events. The rest of the time it contains only gas (primarily air) in the pore spaces. Water passes through this unsaturated or partly saturated zone until it encounters water-saturated soil, sediment, or rock. The top of this saturated, or phreatic, zone is called the water table. Once it enters the phreatic zone, water becomes part of the groundwater system and flows primarily in response to gravity similarly to surface water but much more slowly.

In all rural and many suburban settings, all household water and even much of the industrial water

Two groundwater professionals sample and test groundwater from a monitoring well. Many groundwater professionals are members of the Association of Ground Water Scientists and Engineers, a division of the National Ground Water Association ([www.ngwa.org](http://www.ngwa.org)). (National Ground Water Association)

is drawn from the groundwater system through a well. In former times, people just dug a hole until it penetrated the water table and phreatic zone. Water was drawn from this shallow zone using a bucket or hand pump. The problem with this method of obtaining water is that the water table is so close to the surface in most populated areas that it is polluted with any number of point and nonpoint pollutant sources. In addition, with the heavy usage in these areas, the level of the water table can fluctuate so much that these wells can run dry at any time. For this reason, most people drill deep wells ranging

from tens to thousands of feet to find reliable sources of drinking water.

Surface water may infiltrate the ground beneath it at any time or in any place and become part of the groundwater system. In some places, the topography drops to a lower elevation than the water table. In this case, springs of flowing water emerge. In this way, groundwater may contribute to the surface water system. In other areas, a small lens of clay or other aquiclude material may trap the infiltrating water in a small underground pool that is above the regional water table. This small feature is a perched

**Gulf War oil spills Kuwait January–February 1991** *Air, Water, and Soil Pollution* One of the most vivid images of Operation Desert Storm, or the Gulf War, as it is also known, is of the thick, billowing, black smoke clouds emanating from the giant flares shooting hundreds of feet in the air from the sabotaged Kuwaiti oil wells. It was the biggest oil spill that ever occurred in the world and perhaps the worst environmental disaster. Ecologically, the area may never recover from pollution caused by all of the spilled oil and soot tar from the partially burned oil. It is almost beyond comprehension that this disaster was purposefully caused. The images were so striking that they were used in several popular movies. Most notable of these is *Jarhead*, which shows many aspects of the fires and fallout.

### BACKGROUND

On August 2, 1990, Iraqi armed forces invaded Kuwait, ostensibly to reunite this country with Iraq after the illegal separation of the two nations by the British in 1913. Most experts agree, however, that

the true underlying causes for the invasion were Kuwait's insistence on the repayment of the \$14-billion Iraq had borrowed to finance its eight-year-long war with Iran and economic incentives associated with the annexation of Kuwait's massive oil reserves. Within a few days of the Iraqi invasion, Kuwait's relatively small army had been destroyed, its government was dissolved, and its monarchy was in hiding or exile. It took the United States, working through the United Nations, about seven months to build enough international support among Iraq's Arab neighbors, Russia, China, and Western European countries to muster the use of force to expel Iraq from Kuwait. The first step in that process, the air war, began early in the morning on January 17, 1991, and lasted almost 40 days. On February 24, U.S. and international coalition forces began their land offensive, which ended three days later with Kuwait liberated and the Iraqi army in headlong retreat to their own country.

War has always had environmental consequences, some intentional and some not. In 1672, in order to slow the advance of a French army, the Dutch opened their dikes and intentionally flooded much of their country. While they were successful in staving off the French, the flooded land had been contaminated with salt water and could not be farmed until many years later. China, in 1938, purposefully destroyed the Huayuankow dike on the Yellow River near Chengchow with the intention of trapping and killing several thousand Japanese soldiers billeted in that area. Unfortunately, these same floods also killed tens of thousands of Chinese citizens. Oil spills along the East Coast of the United States at the start of World War II were commonplace as German U-boats sank merchant vessels carrying fuel and other supplies to the British, and the environmental legacy of the U.S. nuclear arms race can be seen at numerous contaminated military bases and manufacturing facilities across the nation. In Southeast Asia, by 1983, the use of the herbicide Agent Orange had contaminated about 50 percent of Vietnam's forests and arable land, many of which today are still struggling to return to productive use.

### POLLUTION OF THE AREA

Shortly after the international coalition began its air war against Iraq, the Iraqi army scuttled five oil tankers moored at the port of Mina Ahmadi, Kuwait's main oil shipping facility, and then blew up an offshore oil loading terminal on Sea Island, another major oil transfer and tanker embarkation point. Both actions created very large oil slicks in the Persian Gulf, almost twice the size of the world's

previous largest slick, the Ixtoc I oil well blowout in the Gulf of Mexico. As coalition air attacks continued into February, the Iraqi army maintained their program of intentional environmental degradation, damaging oil distribution centers in Abu Halifa and Shuaiba and bypassing safety systems on land-based wells so that oil would gush to the surface and form enormous oil lakes or pools. Unlike in the historical examples, there was no strategic or military advantage that Iraq obtained by fouling Kuwait's coastline, soil, or atmosphere: The coalition forces' air war did not stop, the land invasion was not delayed nor its objectives changed, and international opinion did not suddenly begin to favor Iraq.

The oil slick created by the release of an estimated 11 billion barrels of oil (440 million gallons [2.1 billion L]) from coastal terminals and land-based oil wells contaminated a 300-mile- (483-km-) long stretch of beach along the northern coast of Saudi Arabia. Salt marshes, mangroves, coral islands, and other important wildlife habitats and breeding grounds were destroyed, and more than 30,000 seabirds were killed, along with thousands of shorebirds. The local fishing industry was shut down, as oil could be seen from horizon to horizon across much of the gulf in this area. It was only through quick action by the Saudi Arabian government that oil was prevented from entering the intakes of its largest desalinization plants, which supply 40 percent of its potable and industrial freshwater.

Although the extent of the damage caused by the Gulf War I oil slicks is still being evaluated, many experts are convinced that the environment in this area will be unable to recover and that a significant and permanent reduction in species diversity has occurred. What this means for the ecosystem in the Persian Gulf as well as other, worldwide ecosystems is not clearly understood. Despite the severity of the long-term damage from the oil slick, it was quickly overwhelmed by short-term impacts from the oil well fires.

Kuwait operated an inventory of approximately 1,100 preinvasion land-based oil wells. As the Iraqi army fled Kuwait, it set fire to about 850 of them. The wellheads were dynamited, and oil gushing into the air was set ablaze by the explosion. In some cases, the oil oozed to the surface and saturated the sand around fractured casings and caught fire, forming blazing lakes or pools of fire. Several hundred million gallons of oil were released in this manner, and, at the peak of the fires, Kuwait's economy lost \$2,500 every second. Eventually, almost one-third of Kuwait's surface area was covered by a layer of oil, ranging from a thick, asphaltic material near the well-field fires to a tarry crust downwind of them.

The oil well fires dumped hundreds of tons of particulate, sulfur dioxide, and potentially carcinogenic polycyclic aromatic hydrocarbons (PAHs) into the atmosphere. This airborne pollution was deposited across Kuwait as well as southern Iran and parts of Pakistan and northern India. Black snow was reported in the Himalayas, and the smell of oil could be detected more than 1,000 miles (1,600 km) downwind of Kuwait. Similarly to ecosystem effects, long-term health consequences on the Kuwaiti people or coalition forces exposed to these hydrocarbon residuals are not well understood. Gulf War syndrome, a name given to a collection of diseases and other disorders, including certain types of cancer and brain damage, suffered by U.S. and other troops who served in Kuwait, is thought to be related, in part, to exposure to smoke and chemicals from oil field fires.

### EXTINGUISHING THE FIRES

When efforts to extinguish the fires began, there were 613 burning wells, 76 wells gushing oil, and a total of 788 damaged oil wells. Fires from the burning wells shot flames like blowtorches hundreds of feet into the air. Dense smoke clouds reached into the sky to heights of 0.63–2.5 miles (1–4 km) and extended downwind for hundreds of miles. Around some of the fires, the desert was covered with a black crust, and ponds of oil formed around many of the damaged wells, posing a threat of ground-level fires and pollution of groundwater. A black, oily rain fell from the oil well fires, and there were unexploded land mines, bombs, and shells everywhere. This hostile environment, coupled with the lack of adequate technology, and compounded by shortages of water, electric power, and locally available equipment, made it impossible to extinguish the fires quickly.

The first companies to attempt to extinguish the Kuwaiti oil well fires and cap the wells were the internationally famous Red Adair, Boots and Coots, Safety Boss, and Wild Well Control, Inc., from the United States. OGE Drilling-Kuwait, Inc., coordinated the multiple firefighting teams. The four companies began firefighting activities on March 16, 1991, but after several months of slow progress, the Kuwaiti government decided to enlist more help. Santa Fe Drilling Company joined the effort as the number of firefighting companies grew. By the end of August, firefighting teams from France, Hungary, China, Iran, the USSR, and the United Kingdom had joined in the efforts.

By September 1991, the number of firefighting companies in Kuwait had reached 27. This increased effort led to an increase in the average number of wells capped per day from three in May 1991 to

eight in October 1991. By October 10, firefighters had capped 566 of the damaged wells. By November 9, 1991, all burning wells had been extinguished and all gushing wells had been capped.

The oil well fires were so intense and flowing so fast that firefighters were forced to develop and implement innovative firefighting techniques quickly. In early April 1991, the first fires addressed were extinguished by using seawater. The huge amount of seawater that was needed was taken to the fires from the Persian Gulf through a converted oil pipeline at a rate of 4,000 gallons (15,200 L) per minute. Another innovative method was “raising the plume.” In this case, a metal casing 30–40 feet (9.2–12.3 m) high was attached to the blown wellhead to raise the flame. Liquid nitrogen or water was pumped into the casing to reduce the oxygen supply to the fire. Yet another innovation was to drill “relief” wells into the main burning wells. The relief wells diverted part of the flowing oil and gas and reduced the pressure at the main well, allowing it to be extinguished and capped more easily. Dynamite was even used to relieve wellhead pressure in some instances. One of the most unconventional methods devised

involved the mounting of Mig-21 turbine engines on old Soviet T-62 tanks to shoot high-pressure water and air at the burning well. This method, devised by the Hungarian team, proved to be fairly popular.

# H

## **Haiti    deforestation    Haiti 1980–present**

**Water Pollution** Hispaniola, which was Christopher Columbus’s first landfall in the New World, lies in the northern Caribbean. The island has four separate ecological settings, with about half of its eastern and northern land area historically covered by dense growths of pine, extending to elevations of higher than 6,000 feet (1,829 m) above sea level, thanks to the rich soil, plentiful rain, and mild climate. Also present in the rain shadow in the southern and western portion of Hispaniola is a dry forested region making up about 20 percent of the island, and more pine forest covers the other mountainous parts (approximately 15 percent) of the island. The lowlands are dominated by marshes, flooded grasslands, and savannas surrounded by lakes and lagoons.

Just as the island’s ecological regions are readily distinguishable, so are its political subdivisions. The Republic of Haiti controls the western third of Hispaniola, and the Dominican Republic governs its eastern two-thirds. Haiti was a former colony of France that grew into a republic, declaring its independence in 1804. Haiti’s political institutions have long battled to establish and maintain themselves against external meddling by Germany, Spain, and the United States, as well as their own national army and pervasive internal corruption. Currently, Haiti is a presidential republic, whereby the president is the head of state, while a prime minister manages the government.

The history of the Dominican Republic is not much different. It too threw off the yoke of colonialism in 1844. After briefly rejoining the Spanish empire, in 1865 the Dominican Republic finally achieved its independence. Since then, it has endured invasions by the United States (1916 and 1965) and

slow economic growth limited by a lack of natural resources and a low-yield agricultural system. More recently, the tourism and service sectors of the economy have greatly expanded, and the Dominican Republic has emerged as a developing country with a growing middle class. Further economic expansion may be difficult to sustain, however, unless the country can solve its chronic energy shortages. Similar to Haiti, the Dominican Republic is a democratic republic, where the president is both head of state and head of government. Legislative power lies with an executive branch and the two chambers of the national congress.

## **BACKGROUND**

In general, the Dominican Republic has been the more politically stable of the two. Since the mid-1960s, a system of national parks and preserves has been established and remains in existence today. It is these parks and woodlands, many of which are owned by politically connected private individuals, together with the many unspoiled beaches of the Dominican Republic, that help make this part of Hispaniola an attractive and desirable place for its 9.1 million people to live and do business, and for foreigners to vacation. In Haiti, the higher population density and more fragile political system have placed enormous stress on the local ecology.

Charcoal, one of the principal energy sources in Haiti, is made up primarily of impure carbon and is derived from the removal of water and other volatile constituents from wood. This process involves heating or cooking the wood in oxygen-deficient atmospheres in specially built ovens or earthen kilns. Charcoal (meaning “turn to coal,” a reference to its

**Denuded Haitian landscape (left) compared to Dominican Republic's forests (right), south of Dajabon, Dominican Republic (James P. Blair/National Geographic/Getty Images)**

dark color) also can be made from sugarcane and animal bones. Lightweight, soft, and easily broken, charcoal is 85–95 percent carbon, with residues of ash and other compounds. Charcoal burns hotter (930–1,290°F [500–700°C]), longer, and cleaner than wood (390–750°F [200–400°C]) or coal. Its manufacture, however, is terribly inefficient, especially when done on a cottage industry (“low-tech”) basis. Modern industrial charcoal operations yield about 90 pounds (41 kg) of charcoal for every 100 pounds (45 kg) of wood. When it is done locally, by inexperienced or poorly equipped individuals, recovery rates can drop to 50 pounds (23 kg) of charcoal for every 100 pounds (45 kg) of wood or even less. The process also produces significant air pollution including particulate (smoke), polycyclic aromatic hydrocarbons (PAHs), carbon monoxide, and carbon dioxide, and many others depending upon the wood used.

### DEFORESTATION

Hispaniola has no deposits of oil, natural gas, or coal and must import almost all of the raw materials necessary for energy production. The improving eco-

nomic conditions in the Dominican Republic allow it to meet most of its basic energy needs, whereas impoverished Haiti has great difficulty finding the money to pay for the fuel needed to keep electricity flowing. As a result, biomass fuels such as wood, charcoal, and other organic materials derived from plants and animals have become Haiti's primary energy sources, especially for cooking in rural areas and by the urban poor. This fuel, however, exacts a heavy ecological price. In the early 1920s, almost 60 percent of the Haitian countryside was forested. Today, the landscape has been denuded of trees and vegetation as people have scrambled to collect fuel. Approximately 98 percent of Haiti's forests have been cut down, and the smuggling of wood from protected areas within the Dominican Republic is becoming a serious threat to that country's ecology.

With the removal of the trees, soil is quickly washed away, and agricultural productivity in Haiti has dropped severely. In addition, the use of tree, crop, and animal residues (manure) for fuel prevents these materials from acting as needed soil nutrients, further reducing crop yields and limiting the land's ability to support livestock. Besides soil erosion, the deforestation of Haiti has resulted in catastrophic

American temperate climate rain forest in Oregon (Justin Krug, 2008; used under license from Shutterstock, Inc.)

flooding and landslides. It has also resulted in siltation pollution of the rivers. On September 17, 2004, tropical storm Jeanne struck the north coast of Haiti, triggering a series of devastating mudslides and floods. More than 3,000 people were killed, mostly in Gonaïves, where every building was damaged and more than 200,000 were left homeless. Even though it was a major storm, Haiti has experienced worse rains than those from Jeanne in the past with much less loss of life and property. With trees and other vegetation not available to hold the soil in place, the hillsides surrounding Gonaïves first became quagmires and then fast-moving mud and debris that buried everything in their path.

Two-thirds of all Haitians survive by small-scale subsistence farming, and, with so many so dependent on the land, it could be considered puzzling that deforestation is occurring at such a rapid rate. People, however, desperately need the wood to cook their food and to earn a living by selling charcoal. Haiti is the poorest country in the Western Hemisphere, with 80 percent of its population living in

deplorable poverty. Unemployment is more than 60 percent and the average annual income is only a few hundred U.S. dollars.

### ADDRESSING THE PROBLEM

Since the early 1980s, when deforestation was first recognized as a major threat to the sustainability of life in Haiti, the U.S. Agency for International Development and other governmental and nongovernmental organizations have planted more than 60 million trees, which the Haitians cut down at a rate of about 15 million per year. Replanting projects sponsored by the United Nations, World Bank, and other relief organizations are ongoing, and programs try to promote the use of more efficient stoves and alternate cooking fuel (e.g., propane and solar). The root of the problem is financial. Haiti's forests will not return until its citizens are rescued from poverty and given the tools to rebuild their island's economy.

### Hanford Reservation Richland, Washington 1940s–present Soil and Water Pollution

On December 2, 1942, the famous nuclear physicist Enrico Fermi's team of scientists and engineers, working in a laboratory under the foot of stadium bleachers at the University of Chicago, demonstrated that when a uranium atom undergoes fission (splits), it produces energy and excess neutrons. These neutrons can be used in turn to split more uranium atoms in a self-generating chain reaction. This process would become the foundation upon which America's

**N-Reactor Complex on the Columbia River at the Hanford Atomic Reservation in Richland, Washington, ca. 1978**  
(© Bettmann/CORBIS)

nuclear program was built. This discovery occurred during World War II, and the Allies were concerned that the Nazis would be the first to harness atomic power for use in weapons of mass destruction. It was for this reason that President Franklin D. Roosevelt commissioned the Manhattan Engineering District (MED) to build an atomic bomb before Germany. Employing more than 130,000 people at its peak and costing more than \$27 billion (in 2010 dollars), the infrastructure of the Manhattan Project operated in the following three main facilities:

1. Los Alamos, New Mexico (code named Site Y). This was the main research and design branch of the Manhattan Project and served as its command and control center. The final assembly of the bombs dropped on Nagasaki and Hiroshima was performed at Los Alamos from component parts produced at other sites.
2. Oak Ridge, Tennessee (code named Site X). This 60,000-acre (24,281-ha) facility was developed to produce enriched uranium by gaseous diffusion and conducted plutonium production research. During World War II, it consumed almost 20 percent of all electricity generated in the United States. Natural uranium is made up of three isotopes, U-238 at 99.284 percent, U-235 at 0.7

percent, and U-236 at <0.001 percent. U-235 is the only substantially naturally occurring isotope of uranium that is fissionable by neutrons at critical mass in the proper arrangement. Enriched uranium is defined as uranium having a concentration of U-235 isotope greater than its natural occurrence. Highly enriched, or weapons-grade, uranium contains a U-235 concentration greater than 85 percent.

3. Hanford, Washington (code named Site W). Located near the Columbia River, this almost-700-square-mile (1,813-km<sup>2</sup>) facility produced the plutonium for the Hiroshima bomb as well as most of the plutonium contained in the 60,000 other atomic weapons that eventually formed America's atomic arsenal.

As the arms race expanded during the cold war, a second plutonium production facility, the Savannah River Site, was built in South Carolina in the 1950s. These four facilities became the lifeblood of America's nuclear program during the cold war and operated as small cities on 24-hour-per-day production status. If the nuclear deterrent was the reason that there was never a direct war between the United States and Soviet Union, the efforts of these federal nuclear facilities provided that deterrent.

### CONTAMINATION ISSUES

Uranium was the fissionable material used in the first atomic bomb dropped on Hiroshima, and the separation and concentration of U-235 from natural uranium entailed an elaborate and expensive process. While this work went on at Oak Ridge, a second source of fissionable material was sought that could be made faster, less expensively, and more simply. Site W at Hanford, 20 miles (32.2 km) from Yakima, Washington, was chosen by Army General Leslie Groves as the place to build the first plutonium production facility in the United States.

Plutonium occurs naturally only in trace quantities, but if uranium is bombarded with neutrons, it is formed through a beta decay process (conversion of a neutron in an atom's nucleus into a proton and electron) that first forms neptunium and then plutonium by the follow reaction:

During fission, plutonium releases more heat and neutrons than U-235 and thus results in a much larger release of energy for a much smaller mass of fissionable material. For example, 2.2 pounds (1 kg)

of plutonium consumed (fission over three years) in a conventional nuclear reactor can produce enough heat to generate about 10 million kilowatt-hours of electricity. The sudden complete fission (detonation) of the same 2.2 pounds (1 kg) produces an explosion equal to about 20,000 tons (18,144 metric tons) of trinitrotoluene (TNT).

Plutonium was manufactured for weapons production in Hanford in special nuclear reactors. Uranium fuel rods were bombarded with neutrons, and once the maximal amount of plutonium was produced, workers removed the fuel rods (now called spent fuel) from the reactor. The spent fuel rods were extremely radioactive, and the process for recovering the plutonium used only remote-controlled equipment. The plutonium was recovered chemically by PUREX, a plutonium and uranium recovery process that employs extraction. The PUREX process was

used to remove uranium, plutonium, and other fission products from the spent fuel rods. The rods were dissolved in nitric acid with the liquid filtered to remove the insoluble solids (grit). An organic solvent composed of tributyl phosphate (TBP) and kerosene was used to precipitate uranium and plutonium, while the remaining fission products remained in the aqueous nitric phase. Once separated, further chemical processing divided the heavier plutonium from the uranium.

Efficient, reliable, but expensive (it is estimated that five pounds [11 kg]) of plutonium cost between \$10 million and \$40 million to manufacture), the plutonium production activities at Hanford required large quantities of water, both for cooling the reactors irradiating the uranium and for chemical processing. The presence of the Columbia River, which flows for a 50-mile (80.5-km) stretch along the

**Block diagram showing the radioactive pollution from the Hanford industrial site infiltrating the surface and flowing in the groundwater and into the Columbia River. The inset map shows the location of the Hanford site in the state of Washington.**

northern and eastern boundary of the Hanford site, was one of the main reasons why this area was chosen as the host site for plutonium production operations.

During the cold war, the Hanford Nuclear Reservation, the Hanford Project, the Hanford Works, or the Hanford Engineer Works, as the site was called at various times and under various conditions, expanded; eventually it included almost 400 miles (644 km) of paved roads, 160 miles (258 km) of railway lines, and four electrical substations. By the early 1960s, nine nuclear reactors were operating at the site along with five PUREX reprocessing plants, and the facility operated and maintained more than 900 support buildings and numerous radiological laboratories. After 43 years of operation, the last reactor was turned off in 1987 as the cold war slowly approached the end (1989 officially). During its life, Hanford had produced about 60 tons (54.4 metric tons) of plutonium.

### CLEANUP PLANS

The handling and processing of such hazardous materials left behind an environmental legacy that makes part of the Hanford Reservation one of the most contaminated places in the United States. Plutonium production ceased at Hanford in 1989, and the mission of the site changed from weapons production to environmental restoration. Despite almost 20 years of often-remarkable progress, the Hanford cleanup remains a daunting task. More than 40 million cubic yards (30.6 million m<sup>3</sup>) of radioactive waste was present on the site, along with almost 140 million cubic yards (107 million m<sup>3</sup>) of soil and debris contaminated with both radiological and hazardous constituents. Some 500 billion gallons (1,893 billion L) of process wastewater was discharged to the soil, and more than 80 square miles (200 km<sup>2</sup>) of groundwater has been contaminated with both radionuclides and industrial chemicals. The cleanup, which is being done by the U.S. Department of Energy (DOE) and its contractors under the oversight of the U.S. Environmental Protection Agency (EPA) and the Washington State Department of Ecology, has been organized as a Superfund site under the National Priorities List (NPL) to address the following four areas:

1. **100 Area:** This is a 26-square-mile (67.4-km) parcel along the Columbia River, where, between 1943 and 1963, nine water-cooled plutonium reactors were built and began to operate at six locations. The 100 Area reactors are being secured by

“cocooning.” This process involves demolishing supporting structures, then sealing and surrounding the reactor core and associated shielding by an aluminum- and zinc-coated building.

A major part of the cleanup of the 100 Area involves the K Basins. In these concrete-lined, water-filled vaults, more than 2,300 tons (2,087 metric tons) of spent nuclear fuel was stored. Only a few hundred yards from the Columbia River, the K Basins occasionally have leaked and, because of the deterioration of the spent fuel, now contain a layer of sludge. The spent fuel has been removed and is being reprocessed at another area of the site for eventual shipment to the Waste Isolation Pilot Plant (WIPP), but sludge removal is ongoing and it will be several more years before the K Basins are ready to be drained and decontaminated.

While in operation, the reactors discharged cooling water and disposed of solid wastes in more than 400 waste sites, including trenches, cribs (underground drain fields), ponds, and burial grounds. Leaks in the reactor’s wastewater piping and retention systems contaminated soil and groundwater. Remediation of soil involves excavation of more than 6 million tons (5.5 million metric tons) of contaminated soil and its redeposition in the Environmental Restoration Disposal Facility (ERDF), the secure, on-site landfill constructed at Hanford for the long-term management of its remediation wastes. Soil cleanup operations will be ongoing through at least 2012 and will include relocation and on-site disposal of 10 million tons (9.1 million metric tons) of materials. Pump-and-treat remediation as well as in situ treatment systems are being used to control migration and reduce levels of contaminants in the groundwater.

2. **200 Area:** This area is in the central portion of the Hanford site and covers about 15 square miles (39 km<sup>2</sup>). This area had no disposal locations for radioactive or mixed wastes, but hosts several sites where hazardous wastes including batteries and battery acid—containing lead, sulfuric acid, and ethylene glycol, or antifreeze, were discharged into the environment. In addition, historic discharges, primarily from the uranium processing plant, caused localized soil and groundwater contamination. More than 12,000 tons (10,900 metric tons) of waste was removed from an inactive landfill in this area and relocated to the ERDF. Cleanup of the 200 Area was completed in 1995; however, long-term groundwater treatment and monitoring are ongoing.

3. **300 Area:** This is a former 0.5-square-mile (1.3-km<sup>2</sup>) industrial area that contained a plant used for fabricating uranium reactor fuel as well as research facilities focused on improving plutonium production processes. Although some nuclear-related research continues in this area, the majority of the old laboratories have been deactivated, with the 220 buildings present there either demolished or scheduled for demolition. Liquid and solid wastes from operations in the 300 Area were disposed in unlined surface impoundments or landfills and contain low- to high-activity waste and transuranic (chemical elements with an atomic number greater than 92) contaminated materials. Approximately 840,000 tons (760,000 metric tons) of soil and debris has been removed from the 300 Area and disposed of at ERDF. Groundwater in this area will continue to be monitored to demonstrate that concentrations of solvents and radionuclides (trichloroethene, 1,2-dichloroethene, ammonia, arsenic, benzo(a)-pyrene, cadmium, chrysene, polychlorinated biphenyls [PCBs], thallium, tetrachloroethene, cesium 137, chloroform, copper, and nickel) present exceeding health-based concentration standards continue to decrease. Institutional controls also have been established to ensure that groundwater use is restricted to prevent unacceptable exposures to potential off-site users.
4. **1100 Area:** This area is in the southern portion of the Hanford Reservation and covers approximately five square miles (13 km<sup>2</sup>). It included the central warehousing, vehicle maintenance, and transportation distribution center for the entire Hanford Reservation, as well as a former NIKE missile base and control center for America's first anti-aircraft missile system. Wastes (solvents, paints, and acids) were disposed of in pits, on the ground, and in a landfill. Contaminated soil and waste residues were removed from this area and relocated to the ERDF. Cleanup was completed in 1995; however, long-term groundwater treatment and monitoring are ongoing.

There are numerous other areas at Hanford where remediation is ongoing, and certain locations such as the ERDF and cocooned reactors will never be completely restored to prefacility conditions. There also is a human component to Hanford operations. During manufacturing operations, both workers and nearby residents often were exposed to unacceptably high doses of radioactivity, which damaged their health and long-term quality of life. After

some prodding, DOE has recognized this important public health legacy and established compensation programs to help address those who have been adversely affected.

**Hawaiian Patriot oil spill** **Hawaii February 25, 1977** **Water Pollution** The archipelago of Hawaii was formed by geologic processes that resulted in the slow but massive release of thermal energy from deep within the Earth. Magma was generated from a mantle plume, or "hot spot," and flowed onto the seafloor, forming some of the tallest (submerged) mountains on Earth. The Pacific plate moved over this hot spot, first, forming the Emperor Seamounts, and, then, the Hawaiian Seamounts. About 5 million years ago, Kauai, the first of the Hawaiian Islands, fought its way to the surface. Next was Oahu, and later the islands of Molokai, Lanai, and Maui, all sharing the same volcanic base as Oahu. Finally, 500,000 years ago, the "Big Island" of Hawaii appeared. Today, there are seven active volcanoes on the island of Hawaii, and its main peak, Mauna Loa (elevation 16,684 feet [5,085.3 m] above sea level), would be one of the tallest mountains in the world, if measured from its true base some 30,000 feet (9,144 m) beneath the surface of the Pacific Ocean. The hot spot and plate tectonic movements continue, and 20 miles (32.2 km) to the southeast of Hawaii is an active volcanic area named Loihi where the next island will

Oil storage terminal and refinery, Oahu, Hawaii (tomas del amo/Alamy)

probably emerge, although not for at least another 10,000 years.

### BACKGROUND

Hawaii is one of the most energy-dependent places in the United States. Hawaii has no coal, oil, or natural gas deposits of its own and must import 90 percent of the fossil fuel needed to run its economy. These imports, mostly from Indonesia, are expensive, and Hawaiians pay some of the highest prices for gasoline and electricity in the United States. More than 30 percent of the petroleum Hawaii imports is used to make jet fuel, and the need for this and other refined petroleum products continues to grow.

Hawaii's population is currently 1.3 million and is expected to increase to 1.6 million by 2030. Oahu currently has a population density (1,650 people per square mile [644 per km<sup>2</sup>]) greater than that of New Jersey, the most densely populated state in the nation. Every day, Hawaii imports more than 140,000 barrels (22.3 million L) of oil and 24,000 barrels (3.8 million L) of refined petroleum products. To process these important energy sources, ports, storage terminals, and pipelines in two refineries on Oahu rival any major mainland facility in Houston

or Louisiana. It was toward one of these refineries that, in 1977, the tanker vessel, T/V, *Hawaiian Patriot* was bound.

### THE ACCIDENT AND OIL SPILL

Although not a supertanker, the *Hawaiian Patriot* was a large single-hulled ship, 846 feet (260 m) long with a carrying capacity of 30 million gallons (about 700,000 barrels, or 113.6 million L) of liquid petroleum. Fully loaded with a cargo of Indonesian crude oil, the ship was approximately 360 miles (579.4 km) west of Honolulu when one of the hull plates developed a crack. Oil began to leak into the waters of the northern Pacific Ocean, and a slick some 50 miles (80.5 km) long formed as it continued to steam toward Hawaii, the nearest harbor. On February 25, 1977, the crack worsened, one of the main hull plates of the *Hawaiian Patriot* apparently gave way, and approximately 5 million gallons (18.9 million L) of oil was released. As the thick, viscous fluid surrounded the vessel, smoke began pouring from one of the compartments amidships, and the ship suddenly exploded. The 39-man crew was forced to jump for their lives, and all but one were rescued by a passing merchant ship. Most of the surviving

seamen reported only minor injuries. The *Hawaiian Patriot* burned for a few more hours before eventually sinking, taking more than 25 million gallons (94.6 million L) of oil to the bottom of the Pacific Ocean. Although generally not recognized by most researchers, the loss of the *Hawaiian Patriot* was one of the largest oil spills at sea, equivalent to the *Torrey Canyon* disaster in 1967.

### THE ECONOMIC IMPACT

The environmental consequences of the *Hawaiian Patriot* disaster were never fully evaluated. The accident was so far from land that no impacts to Hawaiian beaches or shoreline habitats were observed. The surface slick was dispersed within a few days by natural degradation mechanisms, winds, waves, and evaporation, and no studies were conducted to assess potential impacts on ocean floor environments. There did not seem to be much of a short-term ecological impact from the sinking. The ship's insurers paid a claim for \$12 million, for the loss of the oil, and the crew and captain were reassigned to other vessels. The sinking of the *Hawaiian Patriot* was cited by the then president Jimmy Carter as one of the major reasons why oil tanker regulations, including upgrading of radar systems and more frequent safety inspections by the Coast Guard, needed to be toughened.

Although Hawaii still satisfies the majority of its energy needs by the importation of fossil fuels, steps are under way to make the islands more self-sufficient. Approximately 85 percent of Hawaii's electricity is generated through the burning of oil, and the remaining 15 percent is from such alternate energy sources as biomass from sugar plantations and municipal solid waste, hydroelectricity, wind, and geothermal sources. Plans are under way to increase the percentage of renewable energy electrical generation to 20 percent by the year 2020 through the use of such developing technologies as solar and ocean wave/current converters.

**HCB (hexachlorobenzene)** HCB is a very dangerous substance because it is very persistent and tends to concentrate in animals and build its way up the food chain: It was banned for most agricultural uses in 1965, in part, because it was becoming prevalent in human breast milk. Further, the infants and small children affected were showing adverse health effects from this exposure. Before the ban, HCB was marketed under several names including Hexa CB, Phenyl perchloryl, Perchlorobenzene, Pentachlorophenyl chloride, Anticarie, Bunt-cure, Co-op hexa, Julin's carbon chloride, No bunt 40, No bunt 80, Sanocide, Snieciox, Smut-go, Granox nm, and Voronit C. Even though it is much less common than it was before the ban, it is still ranked the 93rd most dangerous chemical of 275 entries on the 2007 CERCLA Priority List of Hazardous Substances. It has been found in at least 107 of the 1,613 current or former U.S. Environmental Protection Agency (EPA)-designated Superfund sites where it was tested. It is the basic properties of HCB that make it such a danger to public health.

### PROPERTIES, USES, AND PRODUCTION

Hexachlorobenzene is an organic compound under the classification of chlorinated hydrocarbons that does not occur naturally. It typically exists as a white crystalline solid that may be needlelike in form. Commercial production of HCB began in 1933 in the United States but was greatly increased in 1945, when it became a popular fungicide for seeds. It was widely used on onions, sorghum, wheat, and other grains until 1965, when, as the result of adverse health effects, it was restricted and later banned for this use. It was also used to make electrodes, fireworks, ammunition, and synthetic rubber and as a chemical intermediate in the production of certain dyes and other organic chemicals.

HCB was purposefully produced in the United States until the late 1970s. In 1975, only 3,200 pounds (1,455 kg) of HCB was produced compared

with the millions of pounds of annual production prior to 1965. In 1972, 2.5 million–4.9 million pounds (1.1–2.23 million kg) of HCB was produced as an unwanted by-product during the production of chlorinated chemicals, but only 7,770–25,350 pounds (3,532–11,523 kg) was produced in 1984. It is also a by-product in the synthesis of several common chlorinated solvents and pesticides such as trichloroethylene (TCE), carbon tetrachloride, and others. In 1982, imports were reported to be 38,000 pounds (17,272 kg), and 58,000 pounds (26,364 kg) changed hands in 2000.

### ENVIRONMENTAL RELEASE AND FATE

HCB causes extensive damage when released to the environment but is most noted for its persistence. If it is released to the soil, HCB will adsorb strongly onto clay and organic particles and remain fixed. It will not leach into groundwater easily nor biodegrade appreciably. In one study, removal half-life of HCB was found to be 1,530 days (4.2 years), but it can vary between three to six years depending upon conditions. If it is released to surface waters such as lakes, rivers, and streams, that which remains at the surface will evaporate relatively quickly with a removal half-life of about eight hours. Most of the HCB, however, will strongly adsorb to the suspended particles in the water and settle to the bottom, becoming part of the sediment. This fraction will remain fixed for extended periods, with a removal half-life in the range of 2.7–5.7 years depending upon conditions. It will undergo minimal biodegradation. HCB may be released directly to groundwater, where it will undergo extremely slow breakdown with a half-life 5.3–11.4 years. If HCB is released to the air, it will exist primarily in the vapor phase or attach to particles. Breakdown as the result of chemical reaction with photochemically produced hydroxyl radicals has an estimated removal half-life ranging from 0.63 to 6.28 years (average two years) depending upon conditions. Otherwise, it may also be washed out of the atmosphere from precipitation events. As a result, HCB can travel long distances on a global scale and has been detected in glacial ice at the Poles.

HCB is very toxic to aquatic organisms and is a strong bioaccumulator. It accumulates in freshwater fish with log bioaccumulation factors of 3.7–4.3 for trout, 3.1–4.3 for sunfish, and 4.2–4.5 for minnows. Through this mechanism, HCB enters the food chain and can ultimately be ingested by humans.

According to the EPA's Toxic Chemical Release Inventory, in 1987–93, direct manufactured HCB releases to land and water had fallen to 1,287 pounds

(585 kg), all of which was to water and primarily in the states of Louisiana and Texas, though total releases (by-product to land, water, and air) between 1988 and 1999 ranged from 12,600 pounds (5,715 kg) to more than 1 million pounds (28,350 kg) per year. Since then, the EPA Toxic Release Inventory has listed a total release of 28,125 pounds (12,784 kg) in 1999 and 42,555 (19,343 kg) in 2005. These releases were primarily from the alkali, chlorine, and agricultural chemical industries to land and water. Estimates for release of HCB to the air ranged from 46,300 to 63,900 pounds (21,000 to 28,980 kg) per year in the past, but some estimates place the release of by-product HCB at 2–5 million pounds (0.9 million–2.3 million kg) per year.

### HEALTH EFFECTS FROM EXPOSURE

There are numerous adverse health effects from exposure to HCB, several of which are severe. Acute exposure to HCB produces skin lesions, muscle weakness, convulsions, and nerve and liver damage depending upon the level. High-level exposure can be fatal. Chronic long-term exposure to HCB can cause liver and kidney damage, problems with reproduction, and the development of tumors, especially on endocrine glands. HCB can also damage the thyroid and nervous system and, in laboratory animals, the bones and blood, and the immune and endocrine systems. There was a case in Turkey in which a large group of people ate grain for a long period that was accidentally contaminated by HCB. The result was that there was a high death rate in young children of mothers who ate the grain and in young children who ate it themselves. Infants who nursed from mothers who had eaten the grain were found to have elevated HCB from the transfer through breast milk. These infants suffered from a liver disease called porphyria cutanea tarda, the main effect of which is slowed or stopped formation of the oxygen-carrying part of hemoglobin in red blood cells. This disease can cause symptoms of red-colored urine, skin sores, change in skin color, arthritis, and problems of the liver, nervous system, and stomach. The skin sores are another disease, called pembe yara, or “pink sore.”

The U.S. Department of Health and Human Services classified HCB as reasonably anticipated to be a human carcinogen, and the International Agency for Research on Cancer (IARC) classified HCB as possibly carcinogenic to humans (group 2B). EPA determined that it is a probable human carcinogen. These classifications are based upon laboratory studies in which several animals had an increased incidence of liver, kidney, and possible thyroid tumors through exposure to HCB.

## REGULATIONS ON HUMAN EXPOSURE

There are several federal regulations governing public exposure to HCB. The EPA recently set a limit for HCB in drinking water at one part per billion (ppb) under the Safe Drinking Water Act. Prior to this, there were guidelines for drinking water that it not contain more than 0.05 part per million (ppm) in water that children drink and should not exceed 0.2 ppm in water that adults drink for longer periods (approximately seven years). They further require that a spill or leak of 10 pounds (4.5 kg) of HCB or more be reported to the National Response Center. The National Institute of Occupational Safety and Health (NIOSH) estimates that 4,400 workers were exposed to HCB from 1972 to 1974 but only 1,038 from 1981 to 1983 through their occupational health surveys.

**HCB (hexachlorobutadiene)** If an environmental contaminant could be considered to fly below the radar, it would be HCB. It is a by-product and used as a chemical intermediate in the production of

chlorinated solvents, trichloroethylene (TCE), tetrachloroethylene (PCE), chlorofluorocarbons (CFCs), carbon tetrachloride, and other very dangerous environmental contaminants. It is, therefore, found together with these other chemicals and, as such, largely overlooked. The epidemiological studies and even the animal exposure studies are few and confounded by the presence of the other compounds. It has only been relatively recently that HCB has been identified as a possible danger. Yet it is ranked number 22 on the 2007 CERCLA Priority List of Hazardous Substances, which contains 275 entries. It is now regarded as more dangerous than many very dangerous substances. HCB is also known as Hexachloro-1,3-butadiene, Perchloro-1,3-butadiene, Perchlorobutadiene, Dolen-Pur, and GP-40-66:120. It has been identified in 45 of the first 1,350 EPA-designated Superfund sites (National Priorities List) for which it was tested.

## PROPERTIES, USES, AND PRODUCTION

HCB is a synthetically produced chlorinated alkene that is in the form of a clear, colorless, oily liquid with a turpentine odor. It is used as a solvent, heat transfer liquid (largely in transformers), hydraulic fluid, gyroscope fluid, and lubricant and in the manufacture of rubber compounds as well as those already listed. It was also used as a fumigant in other countries. It is estimated that between 7 million and 14.5 million pounds (3.3–6.6 million kg) was produced annually in the United States, but most of the HCB consumed domestically was imported from Germany. The world production of HCB was 22,000 tons (20,000 metric tons) in 1982.

## ENVIRONMENTAL RELEASE AND FATE

HCB is largely released to the environment by dumping, leaks, and spills at manufacturing, storage, and transfer facilities for both HCB and many volatile organic compounds (VOCs), and, therefore, it is primarily a point source pollutant. In 1997, the Toxics Release Inventory reported total production waste of HCB of 8.4 million pounds (3.8 million kg), and in 2006 it was 1,077 pounds (493 kg). It is released to the atmosphere by evaporation, smoke-stack emissions, and incineration. It is slowly broken down by photolysis and reaction with photochemically produced hydroxyl radicals. It can also attach to particulate and be dispersed in the atmosphere. Estimates for the atmospheric half-life for HCB range from 60 days to 2.3 years. In surface water, HCB is removed by slow evaporation from the surface or adsorption onto suspended particulate matter

and subsequent settling into the sediment, where it remains fixed. Evaporation is enhanced by water turbulence, but it is relatively slow. In soils, it adheres strongly to clay and organic matter and is relatively immobile in most soils. In sandy soils, however, it can be moderately mobile. HCBd can biodegrade under aerobic conditions, but there are no studies documenting the rate at which this occurs.

HCBd is moderately to highly toxic to aquatic life, especially crustaceans and fish. Studies have shown that HCBd can bioconcentrate in fish by factors of 5,800–17,000 ambient levels in certain species. Shellfish are also susceptible to bioaccumulation. There is no evidence, however, that it biomagnifies up the food chain. One study showed that in birds exposed to HCBd, decreased survival of chicks resulted, but there is very little information on this point.

### HEALTH EFFECTS FROM EXPOSURE

HCBd is considered to have moderate to high oral and inhalation toxicity, but there is no information for humans, just laboratory animals. Acute exposure may produce several adverse health effects including eye, nose, and skin irritation; difficulty in breathing; pulmonary irritation; damage to the kidneys and adrenal cortex; and death if the dose is high enough. Long-term, chronic exposure may produce damage to the kidneys and liver, anemia, weight loss, and increased mortality rate in many laboratory animals. It also causes retardation of fetal growth in pregnant animals and decreased birth weight. Rabbits also exhibited brain damage as a result of HCBd exposure. The International Agency on Cancer Research (IARC) has assigned HCBd to group 3, not classifiable as to its carcinogenicity to humans. The EPA has labeled it a possible human carcinogen. Results of studies of laboratory animals are equivocal but indicate a general enhanced risk of kidney cancer, benign lung and uterine tumors, and metastatic cancer of the lungs. In humans, an increase in mutations of blood cells was found. It was also found that HCBd causes genetic mutations and chromosomal aberrations in a variety of cells under laboratory conditions, a finding that supports the cancer evidence.

### REGULATIONS ON HUMAN EXPOSURE

The adverse health effects caused by exposure to HCBd have led federal agencies to regulate it. The EPA recommends limitations on exposure to HCBd in drinking water at 0.3 milligram per liter for periods up to 10 days and long-term exposure of 0.1

milligram per liter for children and 0.4 milligram per liter for adults. They further require that any spill or leak of one pound (0.45 kg) or more of HCBd be reported to the National Response Center. The Occupational Safety and Health Administration (OSHA) limits workplace air to a permissible exposure limit (PEL) of 0.02 part per million (ppm) HCBd for an eight-hour workday in a 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) sets the same amount for their recommended exposure limit (REL).

**HCH (hexachlorocyclohexane)** There are eight isomers of the synthetic organochlorine HCH including alpha-, beta-, and delta-HCH. The most infamous of these is gamma-HCH, which is otherwise known as lindane, a very powerful insecticide. Lindane became famous because it concentrates in human breast milk. As the result of use in rice fields, levels as high as 6,500 parts per billion (ppb) of HCH were found in milk fat from China and Japan in the 1970s. Considering the current U.S. Environmental Protection Agency (EPA) drinking water standard is 0.2 ppb, these human milk contents are alarming and led to strong regulatory action, which has since greatly decreased those levels worldwide. Lindane has some trade and synonymous names including Agrocide, Ambrocide, Aparasin, Aphitiria, BoreKil,

Borer-Tox, Exagamma, Forlin, Gallogamma, Inexit, Isotox, Jacutin, Kwell, Lindafor, Lindagronox, Lindaterra, Lindatox, Lorexane, New Kotol, Noviagam, Quellada, Silvanol, Steward, Streunex, and Tri-6 and inappropriately as benzene hexachloride and its trade names Benesan, Benexane, and BHC. Even though lindane has not been produced in the United States since 1977 and has been highly restricted since 1983, it is still a persistent environmental threat, as are several of the other isomers. Of the first 1,662 EPA-designated Superfund sites (National Priority List), alpha-HCH was found in 146 sites, beta- in 159, gamma- in 189, and delta- in 126 sites of those for which it was tested. On the 2007 CERCLA Priority List of Hazardous Substances, gamma-HCH ranks number 32, beta-HCH ranks number 36, delta-HCH ranks number 43, alpha-HCH ranks number 115, and technical grade HCH ranks number 148 of the 275 worst pollutants.

### PRODUCTION AND USE

Lindane is a white or clear crystalline powder that is soluble in water and that may evaporate. It was first manufactured in the United States in 1945, and production peaked in the 1950s, when more than 15 million pounds (6.8 million kg) was produced. Even though it has not been produced in the United States since 1977, it is still imported in some compounds and formulated into others. In 2000, there were 18 suppliers in the United States. It has traditionally been used as an organochlorine insecticide and fumigant for soil-dwelling and plant-eating insects. It has been used about 95 percent for agricultural purposes including for rice and grain but also in warehouses, as seed treatment, and in control of insect-borne diseases. Currently, lindane is still used for treating seeds as well as preventing wood-inhabiting beetles; in flea dip for pets and livestock; for soil treatment; on fruit and nut trees, vegetables, timber, and ornamental plants; and for wood protection. It is also used for lotions, creams, and shampoos that help control lice and mites.

### ENVIRONMENTAL RELEASE AND FATE

As a commonly used insecticide, HCH was widely released as a nonpoint source pollutant from agricultural applications, as well as a point source pollutant from manufacturing and disposal sites. The most common pathway is in surface water from agricultural and residential runoff or industrial spills, dumping, and transfer and disposal leaks. Unless the surface water is highly agitated where the removal half-life is as short as 1.5 days, lindane does not

evaporate readily. Experiments show a removal half-life of 115–191 days for water deeper than three feet (1 m). It does not biodegrade or hydrolyze readily in surface water and photolysis is slow. It typically does not settle into sediment but may concentrate slightly by chemical diffusion. If released to soil, HCH will evaporate from the surface but not at depth. It will not undergo biodegradation under aerobic conditions (field half-life of 15 months) but appears to degrade rapidly under anaerobic conditions. In general, HCH in soil is mobile and leaches slowly and only partially into the groundwater system. Significant numbers of water wells in New Jersey, California, Mississippi, and South Carolina have been found to contain HCH. If released into the atmosphere, lindane will fall out directly, be washed out during precipitation events, or react with atmospheric hydroxyl radicals with a half-life of 1.63 days. It can remain in the atmosphere for up to 17 weeks. The standard monitored period from 1987 to 1993 for EPA's Toxic Release Inventory yielded only 1,115 pounds (506.8 kg) to both land and water because it had already been severely restricted. In 2006, only five pounds (2.2 kg) was reportedly released by industry.

In the natural environment, lindane is moderately toxic to birds at worst but tends to thin egg shells and result in reduced egg production. It is highly toxic to fish and invertebrate species and tends to bioaccumulate to 16–1,600 times the ambient level in mollusks, crustaceans, and some fish. It is also highly toxic to bees and virtually all insects and arachnids. Certain plants (carrots, for example) may preferentially absorb HCH.

### HEALTH EFFECTS FROM EXPOSURE

Exposure to HCH has been shown to cause numerous adverse health effects. Acute exposure to HCH by inhalation or ingestion results in stimulation of the central nervous system, mental and motor impairment, irritability, dizziness, headaches, changes in the levels of sex hormones in the blood, blood disorders (disruption of white blood cells), intermittent and continuous convulsions, pulmonary edema, respiratory failure, and death with increasing levels. It can also be a skin and eye irritant with dermal exposure and may produce some of the more serious reactions of intake exposure. Long-term chronic exposure to HCH has produced kidney, liver, pancreas, testes, ovary, and mucous membrane damage in laboratory animals and even convulsions and death. It was rapidly fatal to dogs in a two-year study. It also increased fetal mortality rate when pregnant animals were exposed. All HCH

isomers are designated as reasonably anticipated to be human carcinogens by the Department of Health and Human Services as the result of experiments on laboratory animals. The EPA has designated lindane (99 percent gamma-HCH) and alpha-HCH as probable human carcinogens. Experiments showed an increase in liver cancer for all rodents and potential increase in thyroid cancer in rats from lindane exposure. One study found that 100 percent of the mice exposed to alpha-HCH developed cancer. Several epidemiological studies of humans found a potential link between increases in lung cancer and leukemia and exposure to HCH.

### REGULATIONS ON HUMAN EXPOSURE

Federal regulatory agencies restrict the use and distribution of HCH. Lindane is listed as a restricted use pesticide by the EPA, which limits the concentration in groundwater to 0.2 ppb under the Safe Drinking Water Act. They further require that spills of lindane of one pound (0.45 kg) and spills of alpha-HCH of 10 pounds (4.5 kg) or more be reported to the National Response Center. Children should not be exposed to more than 1.2 milligrams of HCH per liter of water for more than 10 days. The Occupational Safety and Health Administration (OSHA) regulates workplace air to a permissible exposure limit (PEL) of 0.5 mg of lindane per cubic meter of air for an eight-hour workday in a 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) sets the same amount for their recommended exposure limit (REL) and an immediately dangerous to life and health (IDLH) limit of 50 mg of lindane per cubic meter of air. HCH is banned or severely restricted in more than 60 countries, and lindane is specifically banned or severely restricted in 46 countries.

**heptachlor** Similar to chlordane in many aspects, heptachlor is an organochlorine cyclodiene insecticide that has been highly regulated for many years because of the health and environmental threats it poses. In fact, heptachlor was synthesized by isolating it from chlordane, and it was later banned in 1988 with chlordane, though heptachlor was originally restricted in 1978, about five years earlier than chlordane. Perhaps the most remarkable feature of heptachlor, however, is that a more dangerous contaminant, heptachlor epoxide, is produced by the natural chemical and biological transformation of heptachlor, not in a laboratory but in the environment. Heptachlor epoxide is subject to more stringent environmental regulations than its commercially produced parent. Trade names and synonyms for heptachlor include Aahepta, Agroceres, Hepta, Heptachlordane, Heptagran, Heptamul, Heptox, Gold Crest H-60, Rhodiachlor, Velsicol, Basaklor, Soleptax, and Termide, and even chlordane contains about 10 percent heptachlor. In the first 1,662 U.S. Environmental Protection Agency (EPA)-designated Superfund sites, heptachlor has been identified in 206 and heptachlor epoxide has been identified in 195; however, the number of sites tested for these compounds is not known. As a result of the severe adverse health effects from exposure, even with the ban, heptachlor still ranks number 34th on the 2007 Priority List of Hazardous Substances.

### PROPERTIES, USE, AND PRODUCTION

Heptachlor is a synthetic organic compound that was widely available as a dust, wettable powder, emulsifiable concentrate, and oil solution from its first formulation in 1946 (major distribution in 1953) until its domestic phaseout, which began in 1978 and was completed in 1988. It was used heavily during the 1960s and 1970s primarily by farmers

for the control of termites, ants, and soil insects such as cutworms, maggots, thrips, weevils, and wireworms on crops and in seeds. It was primarily used on corn, wheat, oats, barley, rye, sorghum, citrus, pineapple, and narcissus bulbs. It was also used by exterminators and homeowners to control termites. In pure form, heptachlor is a white or tan powder with a camphorlike odor. Most uses of heptachlor were banned in 1978. Since the second ban in 1988, the only permitted use of heptachlor is as a pesticide for fire ants in buried, pad-mounted electric transformers and in underground telephone boxes and cable television boxes in the southern United States. Heptachlor epoxide was used for a short time as a nonagricultural pesticide in small quantities. Production of heptachlor has varied through the years. In 1971, more than 5.95 million pounds (2.7 million kg) was produced by U.S. companies and primarily used domestically, whereas approximately 100,000 pounds (45,454 kg) was used in the United States in 1982 after the first restrictions were imposed. Production continued after the 1988 ban until 1994 but primarily for export. Export amount of heptachlor was 1.58 million pounds (718,181 kg) in 1992, 2.54 million pounds (1.15 million kg) in 1993, 1.24 million pounds (563,636 kg) in 1994, and 115,000 pounds (53,000 kg) in 1995, and 230,355 pounds (105,000 kg) of remaining stock after production ceased. Heptachlor remains stored in significant quantities in South Carolina, Tennessee, and Texas with lesser amounts in Florida and Ohio.

### ENVIRONMENTAL RELEASE AND FATE

Virtually all heptachlor was released to the environment as a nonpoint source pollutant through application as a pesticide and as a point source pollutant through accidental releases during production, transport, and storage or disposal. Most heptachlor applied to soil surfaces evaporated or underwent hydrolysis in moist soils. Once within the soil, heptachlor attaches itself to clays and organic material and remains fixed, resisting leaching into groundwater systems. It slowly biodegrades and/or oxidizes to 1-hydrochlordene, heptachlor epoxide, and other compounds. Sandy soils have the highest rate of degradation, which is up to 79.5 percent per year, in comparison to 5.25 percent per year for the slowest. Heptachlor epoxide also adheres to soil particles but strongly resists biodegradation and any other form of removal. It has been known to persist for 14–16 years in the upper layers of soil. In surface water, heptachlor evaporates, undergoes hydrolysis reactions to 1-hydrochlordene, or attaches itself to

particles and settles into the sediments. Biodegradation is under anaerobic conditions and slower in water but not as slow as in heptachlor epoxide, which also settles into the sediments and remains fixed. In air, heptachlor and heptachlor epoxide in the vapor phase react with hydroxyl radicals produced through photochemical reactions. Heptachlor epoxide attached to particulate matter and aerosols may travel for great distances before settling to the ground or being washed out by precipitation in even the most remote areas.

Heptachlor is moderately to highly toxic to birds. With heptachlor epoxide, it accumulates in body fat but has also been found in the liver, brain, muscle, and eggs. Heptachlor is highly toxic to bees. It is also highly toxic to fish and freshwater invertebrates such as snails, crayfish, and worms, in which it can bioaccumulate from 200 to 37,000 (average 5,000–15,000) times ambient levels. It is also taken up by plants and is subsequently accumulated in terrestrial animals as well. Human breast milk has been shown to have up to hundreds of times normal concentrations through this process.

### HEALTH EFFECTS FROM EXPOSURE

Heptachlor is classified as moderately to highly toxic through acute exposure by both ingestion and inhalation. Symptoms include hyperexcitation of the central nervous system, irritability, liver damage, loss of coordination, stomach distress, tremors, convulsions, coma, and, in severe cases, death by respiratory failure. Long-term, chronic exposure to heptachlor and heptachlor epoxide resulted in damage to the livers, kidneys, and red blood cells of laboratory animals. Humans specifically suffered blood dyscrasias and increased mortality rate from cerebrovascular disease through prolonged exposure. Increased cataracts have also been reported. They also produce adverse reproductive effects including decreased fertility, delayed development of offspring, and increased mortality rate. The EPA considers heptachlor and heptachlor epoxide to be group B2 probable human carcinogens. They produce an increased percentage of liver cancer in laboratory animals.

### REGULATIONS ON HUMAN EXPOSURE

Heptachlor was identified by Rachel Carson in her book *Silent Spring* as a dangerous pesticide, and the call was taken up by the fledgling American environmental movement. In part for this reason, heptachlor was one of the first pesticides to be regulated. The current EPA drinking water regulations under the Safe Drinking Water Act are 0.4 part per

billion (ppb) for heptachlor and 0.2 ppb for heptachlor epoxide, both of which are comparatively very low. The Occupational Safety and Health Administration (OSHA) limits the amount of heptachlor in workplace air to less than 0.5 milligram per cubic meter of air over an eight-hour workday, 40-hour workweek. Internationally, heptachlor and heptachlor epoxide are banned or restricted in more than 60 countries.

**Hill Air Force Base Ogden, Utah 1987–present Soil and Water Pollution** In 1920, shortly after the end of World War I, in northern Utah, some 30 miles (48 km) north of Salt Lake City and about six miles (9.7 km) south of Ogden, the U.S. Army opened the Ogden Arsenal, a storage and maintenance operation for ammunition, artillery, and mechanized equipment. As World War II

approached, the base began to expand with the construction of four runways, and its operational mission started to shift from ammunition manufacturing and distribution to aircraft operations and maintenance. In 1955, operational responsibility for the base was transferred from the U.S. Army to the U.S. Air Force. Today, Hill Air Force Base (Hill AFB), named after Major Ployer P. Hill, a pilot killed during a test flight of a prototype B-17, is one of the U.S. Air Force's premier operational and mission support centers, occupying approximately 6,700 acres (2,711 ha) on the Weber River Delta, a sloping elevated alluvial terrace that lies about 300 feet (91.4 m) above the surrounding valleys. It is one of the largest employers in Utah with more than 23,000 employees, both civilian and military, and an annual payroll of more than \$800 million.

## CONTAMINATION OF THE SITE

Industrial processes taking place at Hill AFB include those typically associated with the refueling, repair, and maintenance of fighter aircraft, missiles, combat vehicles, and railroad engines. These include storage and dispensing of aviation fuels, metal plating, degreasing, paint stripping, and painting. Various types of chlorinated and nonchlorinated solvents and degreasers, petroleum hydrocarbons, acids, bases, and metals are used and generated as waste products by these operations. In the past, these chemicals and waste products were disposed of according to industry practices in effect at the time. That is, they were discharged to unlined disposal pits and sumps or simply buried in designated areas. By 1980, on-base disposal of hazardous materials had ended, and the air force was working closely with U.S. Environmental Protection Agency (EPA) and Utah's Department of Environmental Quality (UTDEQ) to address legacy soil and groundwater contamination, some of which dates back more than 80 years.

## THE CLEANUP

In July 1987, Hill AFB was placed on the National Priorities List (NPL) as an EPA-designated Superfund site. As such, areas where hazardous liquid and solid wastes generated by installation operations were disposed of could be addressed within this federally approved program. Nine Operable Units (OUs) have been identified at Hill AFB. OUs are waste disposal areas that can be grouped together by location, waste type, disposal method, or some other categorical basis. The status of each OU, in a different stage of investigation or remediation, is described in the following.

### OU-1

OU-1 is on the eastern side of the base and includes two landfills that were used for the disposal of liquid industrial waste and sanitary refuse between 1940 and 1974, two fire training areas where fuel was poured on the ground and ignited and extinguished as part of simulated aircraft fires, two chemical disposal pits where liquid industrial wastes were discharged between 1952 and 1973, a brick-lined waste phenol and oil pit where waste oil and phenols were burned for an 11-year period between 1954 and 1965, and four 20,000-gallon (75,708-L) above-ground tanks (removed in 1985) used for the storage of fuel oil, jet fuel, and hydraulic oil.

Contaminants found in the soil at OU-1 include volatile organic compounds (VOCs), polycyclic aromatic hydrocarbons (PAHs), petroleum hydrocarbons, dioxins, furans, pesticides, and polychlorinated biphenyls (PCBs). The highest concentrations of contaminants were found near the fire training areas and the chemical disposal pits. A layer of light nonaqueous phase liquid (LNAPL) is floating on the water table in the area around the chemical disposal pits and the fire training area that is made up of jet fuel into which base neutral and acid extractable compounds have dissolved, along with dioxins and furans. In addition, PCBs also have been detected in the LNAPL near the chemical disposal pits. A plume of dissolved-phase contaminant constituents also is associated with OU-1 and is made up of dichloroethene (DCE), trichloroethylene (TCE), and arsenic. Fortunately, shallow groundwater is not used for potable purposes on or near Hill AFB.

### OU-2

OU-2 is located along the northern boundary of the base and includes two unlined trenches now covered by a building used in LNAPL recovery, where from 1967 to 1975 unknown quantities of TCE, sludge from solvent recovery units, and vapor degreasers were dumped. In the early 1940s, metal plating tank residues were emptied into these trenches. This area of the base is relatively isolated and infrequently used for military activities.

Soil within the operable unit contains a wide variety of organic and inorganic compounds including solvents, pesticides, and heavy metals. A layer of dense nonaqueous phase liquid (DNAPL) is present in the groundwater underlying the disposal trenches. The DNAPL layer consists primarily of a mixture of chlorinated and nonchlorinated solvents (trichloroethane [TCA], tetrachloroethylene [PCE], methylene chloride, toluene, and Freon) combined with some oil and grease. There are approximately 5,700 gallons

(21,577 L) of DNAPL present in the vadose zone and more than 100,000 gallons (378,540 L) of DNAPL below the water table in saturated sands and clays at the site.

### OU-3

OU-3 is in the southeastern part of the base and includes a vehicle refueling facility and two associated buildings, one for defueling/storage and the other used for a variety of purposes including engine repair and hydraulics and bearing maintenance, that were operated between the 1950s and 1985. Incidental spillage of fuel and solvents has resulted in soil contamination in this area consisting primarily of VOCs (1,1-DCE, PCE, and toluene); base, neutral, and acid extractable (BNAEs) compounds; pesticides (p,p'-DDT); PCBs; and metals. The highest contaminant concentrations are commonly within 10 feet (3 m) of the surface.

Also part of OU-3, are two 12,000-gallon (45,425-L) underground storage tanks that stored sodium hydroxide but were removed in 1992. An estimated 200,000 gallons (757,082 L) of solution was lost, apparently through an undetected leak, during the operation life of these tanks. This release of such large amounts of sodium hydroxide has raised the pH of nearby soil to levels greater than 8.5, which can have both public health and ecological impacts.

An unlined six-acre (2.4-ha) evaporation pond that received storm water and industrial wastewater containing spent solvents, heavy metals, and hydrocarbons is part of this OU. Now filled with construction rubble and capped, this pond was closed in 1986. Soil underlying the former evaporation pond is contaminated with VOCs, primarily benzene and chlorobenzene, BNAEs (dichlorobenzenes 1,2-DCB and 1,4-DCB), PCBs, metals, and cyanide.

No action is planned for the remaining two components of this OU: two small ponds and sludge drying beds that are part of the base's industrial wastewater treatment system. A risk assessment has concluded that the public health and ecological threats posed by the contaminants present at these facilities are below action levels.

### OU-4

OU-4 is a group of several waste management areas near the North Gate of the base. These include two municipal trash-type landfills that ceased operations in 1967 but might contain hazardous materials from prior facility operations, a spoils pit that holds soil and mixed construction debris, and two dump sites, one likely to contain liquid wastes discharged along

the North Gate access road and the other a munitions dump operated as an aboveground storage area during World War II. A plume of trichloroethylene (TCE) has been detected in the shallow groundwater in this area. Concentrations of TCE in this plume are above allowable drinking water quality standards. TCE also was detected in soil at this OU, but not at levels likely to cause adverse health effects.

#### **OU-5**

OU-5 is on the western side of Hill AFB and is made up of two areas, a rail shop and a series of buildings used for munitions and missile storage and rocket motor testing. Cleaning fluids and other chemicals including solvents, petroleum products, and sodium cyanide from railroad engine maintenance activities were discharged onto the ground in an undeveloped area west of the rail shop. Two contaminant plumes, both containing TCE, are present within the shallow groundwater at OU-5. Both are migrating off the base and toward homes in two local communities. Lead, total petroleum hydrocarbon (TPH), and arsenic were detected in on-base soils at this OU, but below levels that are expected to cause adverse health effects.

#### **OU-6**

OU-6 is on the northern side of Hill AFB and was designated after the discovery of groundwater contamination in a nearby residential subdivision. The source of this contamination is thought to be a fuel and waste sludge storage facility along with a suspected leach field. Soil contamination within this OU is not a significant issue, with DCE detected at or below levels that cause adverse health effects. Two contaminant plumes, however, are present in the shallow groundwater of this OU. Both are composed primarily of TCE that has been reported at concentrations exceeding drinking water standards.

#### **OU-7**

OU-7 is in the southeastern section of Hill AFB. It is a collection of areas in the industrial complex of the base and includes two buildings. One, used in electroplating, leaked chromic acid and PCBs into underlying soil. Underground storage tanks were present at the second building, and these tanks were used to collect paint stripping wastes. Apparently, the failure of pipes transferring the waste fluids to these tanks resulted in the discharge of solvents into underlying soil.

#### **OU-8**

OU-8 is in the southern area of Hill AFB. It was formed in 1993 and consolidates all groundwater

contamination present under the industrial complex of the base. It focuses on characterizing and remediating a plume of TCE present in the shallow groundwater.

#### **OU 9**

OU-9 is a catchall category, intended to include other sources of soil contamination that had not been previously identified. This includes areas in the vicinity of actively used buildings where a full investigation cannot be completed until sometime in the future. There are approximately 200 such sites in this category, and others are added if they contain significant contamination that is not already part of another OU.

#### **OU-10**

OU-10 consists of groundwater contamination of TCE at levels above drinking water standards and is present beneath three on-base buildings but also extends off-base toward two nearby communities.

#### **OU-11**

OU-11 is made up of soil and groundwater contamination at three on-base buildings and near the base golf course.

#### **OU-12**

OU-12 includes soil and groundwater contamination related to circa-1970 dumping of drums containing waste solvents and sludge in a two-acre (8,100 m<sup>2</sup>) area. Contaminants detected in the groundwater include TCE as well as carbon tetrachloride. These OUs are still under investigation, and a remedial solution has not yet been developed to address either the on-base or the off-base contamination.

In addition to the OUs listed, Hill AFB is responsible for the investigation and cleanup of several other areas. The Utah Test and Training Range in northwestern Utah and eastern Nevada is the location where Agent Orange herbicide testing and the disposal of ordnance, missile motors, and munitions residues from detonations and/or burns took place and, as a result, has contaminated surface soil. The Little Mountain Test Annex is north of Hill AFB near the Great Salt Lake. Sludge drying beds received industrial wastes from engine testing and missile hardness testing operations as well as phenolic paint strippers from Hill AFB and wastewater from adjacent water treatment plants. Wendover Air Force Auxiliary Field consists of a landfill and other maintenance facilities, and contamination is suspected as a result of solid waste, spent munitions, waste solvents, and suspected ordnance.

## RESULTS OF REMEDIATION

Hill AFB is working aggressively with the EPA and UTDEQ to address each of the OUs, and several have already achieved closure, or “No Further Action,” status. Hill AFB has constructed product interceptor trenches around source areas, installed LNAPL and DNAPL recovery systems to collect separate phase product, and built and operated soil vapor collection systems to help reduce the spread of solvents (especially TCE) on- and off-base.

For example, at one time, Hill AFB stored 100,000 gallons (378,540 L) of JP-4 jet fuel in four 25,000-gallon (94,635-L) underground tanks. Mixing kerosene with gasoline and naphthas makes jet fuels, also called turbine fuels. The result is an aviation fuel that has a high percentage of volatile hydrocarbons and burns much hotter and cleaner than gasoline or diesel fuels. The higher the number, the more kerosene there is in the fuel. JP-4 is the U.S. Air Force’s standard aviation fuel; JP-7 is high flash point special kerosene used in advanced supersonic aircraft. JP-5 is the navy’s standard aviation fuel. It has a lower flash point and volatility and is safer to store and use in the confined, below-deck spaces of aircraft carriers.

In 1989, these underground storage tanks were removed and replaced with aboveground storage vessels. During the tank replacement project, the air force found that JP-4 had been released into the soil. Moving quickly to delineate the extent of the release, the air force found that JP-4 had spread to include an area of soil about 30,000 square feet (2,788 m<sup>2</sup>) to a depth of 35–95 feet (10.7–29 m) below the surface. Depth to first groundwater in this part of the base is about 100–110 feet (30.5–33.5 m) below grade. The Hill AFB is an active facility, and the contamination extended beneath several mission-critical structures including an engine storage yard, fuel yard, and tool maintenance building. The air force decided to use an in situ biostimulation technology called bioventing to remediate the soil.

To grow and reproduce, bacteria need the right combination of moisture, air, nutrients, pH, and temperature. These are called limiting factors, because they control or limit bacterial growth. When a limiting factor is missing or deficient, growth stops and the bacterial population starts to decrease. Whereas it is difficult to change a soil’s pH or temperature, the management of other limiting factors such as moisture, nutrients, and air is more easily accomplished. The introduction or addition of nutrients, water, and sometimes air into soil to stimulate indigenous microbial populations needed to degrade organic pollutants is called biostimulation.

In bioventing, air is slowly injected into the subsurface through specially designed sparging wells.

This provides oxygen to microorganisms in the soil and stimulates bacterial degradation of petroleum hydrocarbon. Not to be confused with soil vapor extraction, which physically strips, or volatilizes, the contaminants, bioventing has the sole objective of providing enough oxygen to stimulate bacterial activity.

At Hill AFB, soil impacted by the JP-4 release had an average total petroleum hydrocarbons (TPH) concentration of almost 900 mg/kg, with some values greater than 5,000 mg/kg, which is close to saturation levels. For four years, beginning in 1991, the air force operated a bioventing system, consisting of one injection well and nine soil gas-monitoring wells. They regularly varied air injection rates to optimize system performance. Soil sampling after four years of system operation indicated that TPH levels had been significantly reduced within a 25-foot (7.6-m) radius of the injection well. TPH levels at the far edges of the plume did not drop, indicating that these areas had probably not been adequately aerated. The air force was so encouraged by these results that it quickly adopted bioventing as one of its major remedial techniques, installing similar systems at more than 140 sites around the country.

### **Hudson River PCB pollution Hudson Falls to Manhattan, New York, New York 1976–present Water and Sediment Pollution**

A capacitor, or condenser, is a passive electrical device that temporarily stores a charge. The simplest of capacitors are made up of two parallel metal plates separated or insulated from each other by a poor or slow-conducting substance called a dielectric. Dielectrics can be made from a variety of materials such as ceramics, glass, plastics, and even certain types of metals. Dry air is a very good dielectric, as are helium, nitrogen, and even distilled water. Commercial capacitors have the plates coiled together into tight, but separate, spirals and are placed inside a barrel-shaped container that has its interior filled by the dielectric.

Capacitors smooth out current fluctuations as an electrical device switches from one task to another. When connected, they are able to provide the extra energy needed to start a large industrial motor and are used in the circuit boards of all sorts of electronic apparatus, including audiovisual equipment, as filters, oscillators, power supplies, and amplifiers.

The key to the way a capacitor functions is the type of dielectric that separates its plates. It is this dielectric that determines, in large part, how much and how quickly the stored electrical charge can be discharged from the capacitor. For large industrial applications, dielectrics initially were wax or petroleum jelly, but trying to fill completely the barrel-shaped vessels that held the capacitors without leaving any voids

proved difficult. In the 1930s, a new type of dielectric was developed by Monsanto, Inc. It was a fluid with excellent stability at high temperatures, a high flash point, and resistance to moisture absorption. It quickly became the dielectric of choice for capacitors as well as electrical transformers. This new product was marketed under a variety of trade names such as Askarel, Aroclor, Pyroclor, and Pyranol, but it was simply a type of chlorinated heavy oil or hydrocarbon. Its common chemical name was polychlorinated biphenyls (PCBs). Available in more than 200 varieties, PCBs were not inexpensive but were widely used not only in electrical equipment but also in many other types of products such as coolants, lubricants, plasticizers, and adhesives.

### **BACKGROUND**

The General Electric Company (GE) quickly recognized the value of this new class of dielectric fluids. The company was founded in 1890 by Thomas Edison as the Edison General Electric Company to commercialize his newly invented incandescent light bulb. Edison merged with a competitor in 1892 and then moved the GE company to Schenectady, New York, to take advantage of the plentiful land and reliable electricity generated by the nearby Hudson River. Today GE is a multinational firm with 320,000 employees. It manufactures everything from jet engines to medical devices and provides a wide variety of commercial and retail financial services. Annual profit in 2006 was \$90 billion with approximately \$160 billion in total revenues. The company is headquartered in Connecticut but has

**General Electric Company capacitor plant in Hudson Falls, New York, 2000 (AP Images)**

**Map of the Hudson River in New York State showing key locations, including the General Electric operations in Hudson Falls and Fort Edward**

centered much of its eastern U.S. manufacturing activities within New York State, especially in the Albany area. In the late 1940s, two GE capacitor manufacturing facilities at Fort Edward and Hudson Falls began to use PCBs in the fabrication, repair, and refurbishing of capacitors and other electrical equipment. As manufacturing operations continued, these plants began to discharge PCB-laden wastewater into the Hudson River.

Originating in the Adirondack Mountains, the Hudson River's main channel is more than 315 miles (507 km) long and drains approximately 13,400 square miles (34,705 km<sup>2</sup>) before emptying into the Atlantic Ocean at the southern tip of Manhattan. The 150-mile (241.4-km) stretch of the Hudson between its confluence with the Mohawk River at Troy, New York, and upper New York harbor is an important commercial waterway. It connects the

New York State Canal system, most notably the Erie Canal, which originates some 400 miles (643.7 km) to the west near Buffalo, to the port of New York.

The river is informally divided into two sections: The Lower Hudson, which is actually a tidal estuary, is the section between the Battery in Manhattan (River Mile 0) and the Federal Dam near Troy at River Mile 153 (246 km). This dam, constructed across the river in 1916, was designed to improve access from the Hudson to the Erie Canal. The Upper Hudson is a 40-mile (64.4-km) stretch of the river between Hudson Falls and the Federal Dam at Troy that is separated into sections by eight smaller dams and locks. These dams provide navigational control for the Champlain Canal, which also is a part of the New York State barge canal system.

The Hudson River has played an important role in not only the economic achievements of the eastern United States, but also its cultural and literary development. In 1996, the U.S. Congress formally acknowledged the value of this important watershed and established the Hudson River Valley National Heritage Area. This is one of only 37 federally designated heritage areas funded and managed by the National Park Service. Its goal is to preserve, protect, and interpret the nationally significant cultural and natural resources of the Hudson River valley for the benefit of the nation.

### POLLUTION OF THE RIVER

The dams and locks on the Lower Hudson served an important role in navigation and commerce, but they also had an unintended environmental consequence. Throughout the postwar years and until 1977, GE's Fort Edward and Hudson Falls capacitor manufacturing facilities legally discharged wastewater containing PCBs into the Hudson River under permits issued by New York State. Although very stable and persistent in the environment, PCBs are not very soluble and are heavier than water. Once released, they tended to accumulate downstream not very far from the plants behind the dam at Fort Edward.

After more than 150 years of service, the dam's owner, Niagara-Mohawk Power, petitioned the Federal Power Commission (FPC), in 1973, for permission to remove the dam, because it had become unstable and could no longer be economically maintained. The FPC agreed, and between July and October of that year the dam was removed. As the reservoir that had been created by the dam drained, and the river channel reestablished itself, the PCB-laden sediments that had collected in the reservoir behind the dam were exposed. These contaminated sediments were concentrated in a 1.5-mile (2.4-km) stretch of the Hudson River, just upstream of the former dam. Spring 1974,

however, was unusually wet, and the Hudson River south of Fort Edward experienced several 10-year flood events, which flushed the PCB-bearing sediments farther downstream. Subsequent flooding and the natural tidal movements of the Hudson River eventually spread the PCBs along its entire length.

PCB discharges from the two GE capacitor plants continued until 1977, and studies by the New York State Department of Environmental Conservation (NYSDEC), the U.S. Environmental Protection Agency (EPA), and GE have estimated that about 1 million pounds (453,592 kg) of PCBs was released into the Hudson River system south of Fort Edward over the 30 years between 1947 and 1977. Although much of the material has been either removed (dredged) by GE or washed out to sea, estimates by the EPA still place the total amount of PCBs remaining in Hudson River sediments at 500,000–660,000 pounds (226,796–299,371 kg).

By the 1970s, public health and environmental officials had become concerned about possible physiological impacts from exposure to PCBs, and there was a growing body of evidence to indicate that PCBs were bioaccumulating and biomagnifying in the environment. The United States and Canada banned the production of PCBs in 1976 and instituted rules for their gradual phaseout and replacement. Most other countries passed similar bans shortly thereafter. Studies have linked PCBs to liver and nerve damage, and there is credible evidence that they may be carcinogenic and cause fetal injury.

In 1976, NYSDEC banned commercial fishing for most of the Hudson River's main species, including striped bass, carp, and perch. Sports fishing was still allowed, but anglers were advised to take a "catch and release" approach and not to eat fish from the river. The New York State Department of Health (NYSDOH) issued an advisory that warned women of childbearing age and children younger than age 15 not to eat fish from the Hudson River south of Hudson Falls. This same advisory recommends that no one should eat any fish caught between Hudson Falls and the Federal Dam in Troy. A 2001 advisory reduced some of these restrictions but still recommends limits on consumption of fish caught in the river. For striped bass, the advisory suggests no more than one meal per month if the fish was caught in the Lower Hudson south of the Tappan Zee Bridge. No striped bass should be eaten if caught in the Upper Hudson.

### THE CLEANUP

In 1984, the Upper Hudson River site, a 43-mile (69.2-km) stretch from the Fennimore Bridge in Hudson Falls (river mile 197 [317 km]) to Federal Dam at Troy (river mile 154 [246 km]) was added

to the National Priorities List (NPL) as a Superfund site. This listing was later expanded to include the Lower Hudson River Site from Troy to the Battery in Manhattan, a distance of about 200 miles (320 km), making the combined Hudson River Site one of the largest Superfund projects in the United States. As part of the NPL process, the USEPA notified GE that the company would be responsible for implementing the measures needed to address the presence of PCB-contaminated sediments in the river.

In September 1984, the USEPA issued a Record of Decision that stated: "A technologically feasible, cost-effective remedial response to PCB contamination in the riverbed that would be reliable and would effectively mitigate and minimize damage to public health, welfare and the environment is not presently available." In other words, any attempt to remove the PCB-contaminated river sediments would cause more harm than good. Although NYSDEC did not agree with this finding, the USEPA concluded that the PCB-laden sediments were being covered over or naturally encapsulated and that, given time, they would become isolated from the environment and no longer pose a significant ecological or public health threat. In the meantime, NYSDEC and GE implemented a series of remedial actions designed to reduce or prevent further migration of PCBs into the Hudson River from its two capacitor plants.

In the mid-1970s, NYSDEC directed the removal of more than 770,000 cubic yards (588,707 m<sup>3</sup>) of PCB-contaminated sediment and related debris from the navigational channel of the Champlain Canal near Fort Edward. These materials were placed in specially constructed spoil pits and buried beneath a low-permeability cover. Throughout mid-1990 and most of 1991, GE capped in situ 50–60 acres (20.2–24.3 ha) of remnant PCB deposits exposed on the banks and shoreline of the Hudson River after the Fort Edward dam had been removed and its reservoir drained.

From late 1997 through September 1998, GE removed 1,100 cubic yards (8,410 m<sup>3</sup>) of debris and sediment containing PCBs from an area near its Fort Edward plant to allow inspection of the underlying bedrock for the presence of PCB seepage. In 1994 and 1995, GE also excavated, from a series of tunnels underneath its Fort Edward plant, 3,400 tons (3,084 metric tons) of sediment that contained approximately 45 tons (40.8 metric tons) of PCBs. As part of this work, breaks and fractures in the bedrock of these tunnels where PCBs were leaking out were grouted and a groundwater collection system was installed to capture PCB-contaminated groundwater that was leaking from underneath the Hudson Falls plant and into the river. By mid-2001, more than 3,000 gallons (11,356 L) of PCB-contaminated water

had been recovered and shipped off-site for disposal. More than 230 groundwater recovery and monitoring wells have been installed to create a hydraulic barrier between the Hudson Falls site and the river. These wells serve to collect both separate-phase PCB liquids and PCB-contaminated groundwater. After treatment, collected groundwater is discharged back into the Hudson River.

As a result of these and other remedial activities mandated by the EPA and carried out by GE, PCB levels in the Hudson River ecosystem have been declining. The highest reported PCB concentrations in Hudson River sediments occurred in the early 1970s; they were due, in large part, to the continuing releases of PCBs and PCB-laden wastewater from the capacitor plants and the Fort Edward dam removal. Average PCB concentrations in sediments near Fort Edward were greater than 50 parts per million (ppm) in 1977 but were reduced to about 10 ppm in 1998. Similarly, PCB concentrations in fish from the Upper Hudson River have declined from about 80 ppm in largemouth bass in the 1970s to about 4 ppm in 1997. The Food and Drug Administration has established a safe tolerance level for PCBs in fish of 2 ppm.

Despite these and other indications of ecological improvement, the EPA and NYSDEC issued a new Record of Decision in 2002 calling for the removal of all PCB-contaminated sediment in the Upper Hudson River with a concentration greater than three grams per square meter. This translates to a total volume of sediments equal to about 1.56 million cubic yards (1,192,706 m<sup>3</sup>). Another 0.6 million cubic yards (458,733 m<sup>3</sup>) of sediment with a PCB concentration greater than 10 grams per square meter is to be removed from a separate stretch of the river. Approximately 0.5 million cubic yards (382,277 m<sup>3</sup>) of PCB removal will also take place from designated “hot spots” of elevated levels. This massive dredging project is to be closely monitored for possible air quality impacts, noise, disruption to river traffic, and resuspension of now-buried PCBs into the ecosystem. Contaminated dredge spoils are dewatered and stabilized at a special nearby processing facility and shipped to a designated disposal site in Texas. The cost of this work, to be paid for by GE, is estimated at around \$500 million.

The decision to implement such a massive dredging program is controversial, and many scientists and researchers doubt that it is necessary or appropriate. They doubt that it will provide much of a public health or ecological benefit. These concerns are based on questions as to whether PCBs are really as harmful as some of the toxicological data indicate. Health effects observed in laboratory animal

studies are difficult to extrapolate to humans. There is a body of evidence that indicates that people must be exposed to much higher levels of PCBs than is present in Hudson River sediments for them to be damaging. Other studies have found that PCBs, once absorbed onto the sediments, may not be leaching or may leach only very slowly into river water and may not be acting as a continuing source of contamination. Finally, some researchers have developed models showing that the chance of large-scale remobilization of PCBs from sediment into the river is low, even in extreme weather events. The money that will be spent to remove the contaminated sediments would be more beneficial to public health and ecological impacts if directed to other environmental needs, such as controlling urban runoff. Research into these and other areas continues, and future findings will no doubt play a role in the final implementation of the dredging program, which began in 2009.

**Hurricane Katrina New Orleans, Louisiana August 23–31, 2005** *Water Pollution* The most costly natural disaster in the history of the United States was spawned in August 2005 in the Atlantic Ocean. Hurricane Katrina strengthened from a tropical depression and tropical storm on August 23 just before it made landfall in South Florida as a

category 1 hurricane. Once it crossed over into the warm waters of the Gulf of Mexico and strengthened quickly to category 5 status on the morning of August 28, it reached its peak strength that day, with maximal sustained winds of 175 miles (280 km) per hour. Katrina swung from its westward track to a northward track heading just east of New Orleans, Louisiana. This was the killer track that residents of New Orleans had been warned about for several decades.

### LANDFALL AND DAMAGE

The powerful left side of the storm pushed a huge storm surge northward onto the Gulf Coast of Mississippi, causing extensive damage there. The leading edge of the storm swept this swelled Gulf of Mexico water westward through the Rigolets, a narrow opening in a thin strip of land, and into Lake Ponchartrain, Louisiana. This huge lake is 35 miles (56 km) long by 25 miles (40 km) wide and lies immediately north of the city of New Orleans. There are a series of earthen levees along the south shore

of the lake to protect the city from storms on the lake. Hurricane Katrina passed just to the east of the lake still at category 3 strength. The full force of the weaker left-side winds heading due south created a storm surge on the now-overfilled lake that swamped the levees and sent a wall of water hurtling southward through the city. This storm surge caused 53 different levee breaches in greater New Orleans and submerged 80 percent of the city.

The damage totals were staggering. At least 1,836 people lost their lives directly in Hurricane Katrina or in the subsequent floods, making it one of the deadliest hurricanes in U.S. history. The storm is estimated to have been responsible for upward of \$81.2 billion in damage, making it, by far, the costliest natural disaster in U.S. history. The city of New Orleans would still not have recovered from the destruction four years later in spite of extensive rebuilding efforts. There was even a sizable faction in favor of abandoning the city forever.

### ENVIRONMENTAL DAMAGE

The city of New Orleans was literally submerged after Katrina passed through. As part of the cleanup effort, the brackish floodwaters were pumped into Lake Pontchartrain by using powerful pumps that operated around the clock. Completing this process took 43 days. When they struck the city, these floodwaters inundated the sewage system and raw sewage spilled out at numerous locations. They inundated numerous homes and businesses and even landfills and cemeteries, leaching an enormous amount of hazardous substances that threatened public health. The residual floodwaters contained a mix of raw sewage, bacteria, heavy metals, pesticides, toxic chemicals, and crude and refined oil, all fermenting together in the hot Louisiana sun. This “toxic soup,” as some called it, was cleaned up by many groups including the military over the next year or more. Great care had to be exercised in handling this waste mainly because of the potential for disease.

The extensive petroleum and petrochemical industry in Louisiana is a great boon to the economy but a great danger during a disaster like the hurricane of 2005. As a result of Hurricane Katrina there were 25 spills of 50 barrels (2,100 gallons [7,980 L]) or more, all of which required remediation, and another 18 spills of this size less than one month later when Hurricane Rita also struck Louisiana. The Department of Homeland Security estimates that the two together totaled six major, five medium, and more than 5,000 minor oil and hazardous material responses at the outset. Additional minor spills continued to be identified and addressed for the

## Hurricane Floyd and Hog Waste in Eastern North Carolina

North Carolina has developed a booming hog farming industry. It grew from 2 million hogs in 1990 to 10 million hogs by 1997, making it the second largest hog producer in the United States. The rapid growth in the 1990s was facilitated by the building of large automated confining farms that housed hundreds to thousands of hogs. The hog farmers formed a politically strong group and were allowed to expand their farms and facilities without restriction. Many of the factorylike farms were built on the floodplains of sizable rivers and in reclaimed wetlands that are environmentally sensitive and prone to flooding. The problem is that each hog produces approximately two tons (1.8 metric tons) of waste per year, and the total yearly output for the entire area was on the order of 20 million tons (18 million metric tons) of waste. Disposal of the waste became a serious issue because there was so much of it and so much of a risk to public health. The solution adopted by the farmers was to build huge unlined lagoons into which they pumped both the liquid and the solid waste. The lagoons were the size of football fields (300 feet [92 m] by 150 feet [46 m]) and filled 10–15 feet (3–5 m) deep in waste.

Environmentalists warned that this situation was a disaster waiting to happen. In this area of North Carolina, heavy rains are common, and it is hurricane prone. There were even a few collapses of lagoons

that sent tons of rotting waste into rivers and through towns, causing not only health hazards but also vile odors, the likes of which are unimaginable. The situation was widely publicized and even appeared on the television show *60 Minutes*. The pressure grew so great that finally, in 1997, a law was enacted to prohibit the building of new waste lagoons on floodplains, and in 1999 the governor of North Carolina proposed a 10-year plan to introduce new technology for waste treatment and to phase out the then-4,000 waste lagoons.

### THE POLLUTION

The problem was that nature did not wait until the cleanup could take place. In late August 1999, Hurricane Dennis struck North Carolina and filled lakes, rivers, and reservoirs to capacity and completely saturated the ground with water. Just two weeks later, the larger and more powerful Hurricane Floyd struck the same area. It produced 20 inches (50 cm) of rain in eastern North Carolina, killed nearly 50 people, forced 48,000 people into shelters, and destroyed 2.3 million acres (931,000 ha) of crops. The environmental disaster resulted from the hog farming industry. Some 38 waste lagoons completely washed out, and 250 operations were flooded or had overflowing lagoons. It is estimated that 250 million gallons (946 million L) of untreated pig waste was dumped into riv-

next year or more. They estimated that more than 9 million gallons (34.2 million L) of oil was released during the major spills alone.

These major spills required extensive treatment and repairs and contributed the largest volume to the pollution problems in the area.

### **Murphy Oil Corporation Refinery: Chalmette, Louisiana**

It is estimated that more than 819,000 gallons (3.1 million L) of oil was discharged during the storm. The vast majority of the oil had been contained within the existing secondary containment unit located on refinery property. Murphy Oil launched an aggressive cleanup effort, and approximately 83 percent of the oil from the spill either had been recovered or had evaporated within one year. Hundreds of homes adjacent to the facility were saturated with oil during the leak. Many of the homeowners accepted a settlement from Murphy Oil, but others initiated a class action lawsuit against them.

### **Shell Pipeline Company: Pilot Town and Port Sulphur, Louisiana**

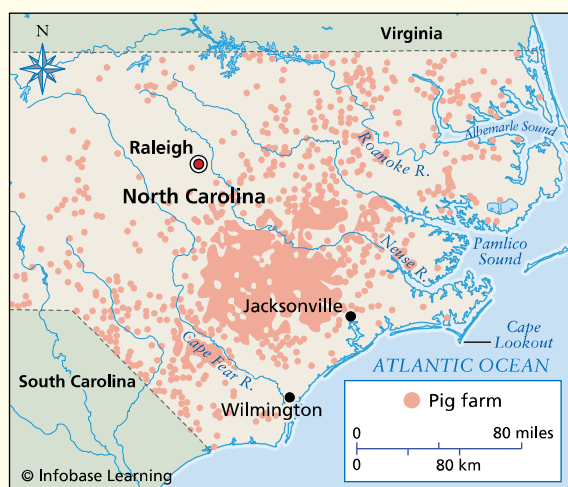

In Pilot Town, crude oil leaked from an above-ground storage tank and into a tank dike and the surrounding area. More than 1.1 million gallons (4.2 million L) was estimated to have leaked, but more than 849,030 gallons (3.2 million L) of it was recovered within one year. In Nairn, Louisiana, some 136,290 gallons (517,900 L) of crude oil leaked from a 20-inch (50-cm) pipeline. Damage to the pipeline resulted from a breach in a hurricane protection levee.

### **Bass Enterprises Production Company: Pointe a la Hache, Louisiana**

Approximately 461,538 gallons (1.75 million L) of oil leaked from storage tanks into the secondary containment system surrounding the tanks during and after Hurricane Rita. Within one year, some 30,660 gallons (116,508 L) had been recovered and approximately 225,330 gallons (856,254 L) was naturally dispersed or evaporated.

ers, creeks, and wetlands. In addition, approximately 30,000 hogs perished along with 2 million chickens and 735,000 turkeys.

Most of the poultry was simply piled up and left to rot. The state sent out mobile incinerators to destroy the decaying hog carcasses, but there were too many and farmers were instructed to bury as many as possible in pits. These pits were supposed to be on dry ground and at least 3.3 feet (1 m) deep, but there was very little dry ground at the time and no oversight on the operations. As a result of the

**Map of eastern North Carolina showing the distribution of hog farms in 2000**

flooded waste and the rotting carcasses, the surface water and groundwater in the area became a mass of bacteria and disease and remained so for months. Residents had to use bottled water or risk disease or even death. The stench that accompanied this disaster has been described as unbearable.

### THE AFTERMATH

Largely as a result of the Hurricane Floyd contamination, in July 2007, North Carolina became the first state in the nation to ban the construction or expansion of waste lagoons and spray fields on hog farms. This ban is part of the legislation in the Swine Farm Environmental Performance Standards Act. The ban is designed to prevent these contamination problems in the event of another hurricane or severe storm.

### **Bass Enterprises Production Company: Cox Bay, Louisiana**

As a result of damage from Hurricane Rita, approximately 3.7 million gallons (14 million L) of oil was released. Within one year, 1.1 million gallons (4.2 million L) had been recovered, and approximately 982,800 gallons (3.7 million L) was naturally dispersed or evaporated.

### **Chevron Empire Terminal and Pipeline: Buras and Port Sulphur, Louisiana**

A significant but unreported amount of oil that was discharged from a storage tank at the terminal at Buras as a result of Hurricane Katrina was naturally dispersed and evaporated. Oil recovery operations and debris cleanup were under way at the time Hurricane Rita struck and had to be suspended, and emergency response personnel had to be evacuated. That is why estimates are uncertain. The pipeline rupture at Port Sulphur spilled approximately 1.4 million gallons (5.3 million L)

of oil, the cleanup of which was also hampered by Hurricane Rita.

### **Sundown West: Potash, Louisiana**

An estimated 13,440 gallons (51,072 L) of oil was discharged from tanks and piping that were ruptured during the storm. Within one year, approximately 7,686 gallons (29,207 L) of the oil was recovered and treated.

### **Sundown East: Potash, Louisiana**

An estimated 18,900 gallons (71,820) of oil was discharged from tanks and piping that were ruptured during the storm. Within one year, approximately 8,400 gallons (31,920 L) had been recovered.

### **Dynegy Venice: Venice, Louisiana**

Dynegy Midstream Services operates the Venice Energy Services Company (VESCO), a natural gas processing facility in Venice, Louisiana. They undertook the cleanup of environmental damage

associated with Hurricane Katrina. Approximately 24,822 gallons (94,324 L) was discharged as a result of storm damage. Within one year, 16,002 gallons (61,000 L) had been recovered and the remaining 8,820 gallons (33,516 L) was contained in a diked and boomed area.

**hurricanes and pollution** When a hurricane that has strengthened over the ocean finally makes landfall (goes ashore), the media cover the accompanying death and destruction as headline stories for as long as there is public interest. Considering the devastating effects of a hurricane on a community and its population, the media attention is appropriate and necessary. In comparison, everything else about the storm is understandably incidental. One of the main incidental aspects of a hurricane is the environmental damage that it does to the community. The effects can be both natural and a result of the destruction of structures. Although potentially severe, these environmental effects are typically reported in less detail than the primary effects of the hurricane. Instead, they are relegated to secondary reports, if reported at all. These environmental effects, however, can be devastating to an area and take several years from which to recover. Indeed, in some cases, they can be more damaging to the community than the primary effects of the hurricane itself.

#### DEVELOPMENT OF HURRICANES

Hurricanes are tropical storms that are considered to be the most powerful meteorological events on Earth. A fully developed hurricane produces and consumes enough energy per day to power the entire United States energy needs for an entire year. These huge storms are only called hurricanes if they occur

in the Atlantic Ocean or adjacent related waters such as the Caribbean Sea and Gulf of Mexico. They are called typhoons in the Pacific Ocean and cyclones in the Indian Ocean. All are produced in the same way and are equally powerful.

Unlike most weather disturbances, such as tornadoes or blizzards, hurricanes are not associated with major weather-producing systems such as fronts or large low-pressure systems. They are not associated with permanent weather-driving features such as the jet stream. Instead, they most commonly begin inconspicuously as a modest cluster of thunderstorms in the Atlantic Ocean, off the west coast of Africa. Rather than being associated with a front or deep low-pressure system, as would be expected for large storms, hurricanes can only develop within large stable air masses with little wind. They can also only develop if the surface ocean water temperature is 79°F (25°C) or greater. At this temperature, the humidity is high in the air above the water surface. This humid air is swept up into the updrafts of the thunderstorms. As it rises, the moisture condenses to form rain, and at this vapor-to-liquid phase, there is latent heat transfer into the storm. This energy added to the storm causes pressure to decrease and the updraft to increase. The winds sweeping into the storm whip up the surface of the ocean water into waves that in turn expose more water surface from which more humidity can be formed. More humidity leads to more condensation and more latent heat transfer in a positive feedback system that powers up the storm.

The growing storm rotates counterclockwise in the Northern Hemisphere as the result of the Coriolis force, which is driven by the rotation of the Earth. In the Southern Hemisphere, tropical storms rotate clockwise. As the result of the momentum of these massive spinning systems, they cannot cross the equator. As the spinning storm grows, it develops a clear spot at its center called the eye of the hurricane that ranges from 20 to 40 miles (32–64 km) in diameter. The eyewall that surrounds the eye is the most dangerous part of the storm, containing the strongest winds and heaviest rains. Outward from the eyewall there are spiral rain bands of five to 10 miles (8–16 km) width and several hundred miles in length. These rain bands define the entire outer part of the hurricane. Hurricanes are typically about 300 miles (480 km) wide but range from 200 to more than 500 miles (320 to 800 km). There is significant wind in the areas between the bands but little to no rain. The location of the heavy clouds and rain in a hurricane shows where the air is rising and thus the lower pressure. Where there is no rain, the air is falling and thus the pressure is higher.

Hurricanes are not tied to major weather systems and fronts and are therefore unguided. This is why it is very difficult to determine the direction and speed that a hurricane will travel and why they can follow such illogical paths. They typically travel at about 15–20 miles (24–32 km) per hour but can achieve speed of 60 miles (96 km) per hour in some instances. In reality, hurricanes are very fragile storms. If they make landfall, travel over ocean with surface temperatures below 79°F (85°C), or encounter a front with high-level winds or another basic weather feature, they will quickly degrade.

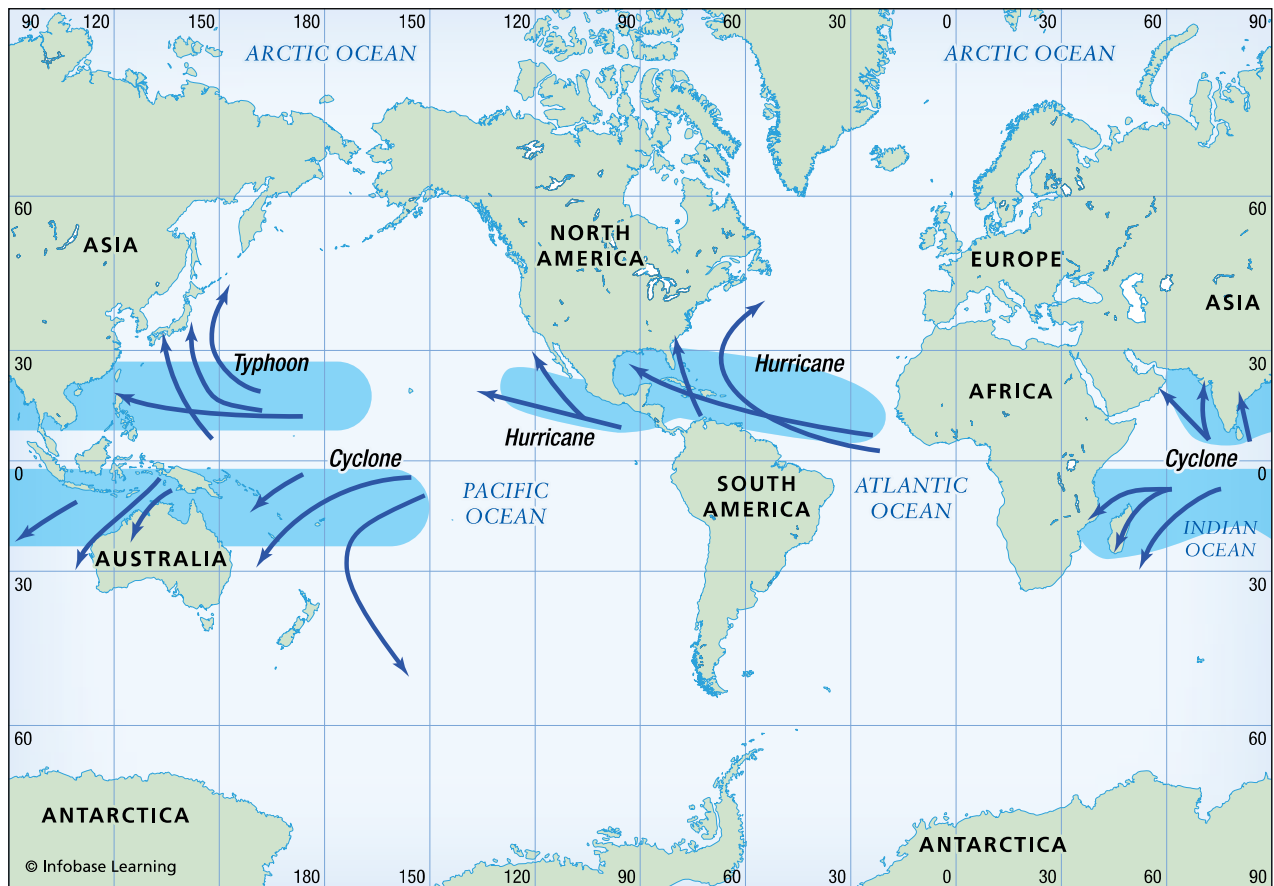

### CLASSIFICATION OF HURRICANES

There are several classification systems for tropical disturbances. The general system divides them into tropical depression, tropical storm, and hurricane classifications. A tropical depression is an organized system of thunderstorms with a defined surface circulation and maximal sustained winds of 38 miles per hour (61 km/h). A tropical storm is an organized system of strong thunderstorms with

surface circulation and maximal sustained winds of 39–73 miles (62–117 km) per hour. A hurricane is an intense tropical weather system of strong thunderstorms with well-defined circulation and maximal sustained winds of 74 miles (118 km) per hour or higher.

The standard system for classifying hurricanes is based on the Saffir-Simpson damage potential scale. This scale is primarily determined by news reports based on the maximal sustained winds but in reality has several factors that are supposed to be evaluated. These factors include the height of the storm surge waves, the inland flooding of ocean water, and the damage done to homes and other structures. The following are five categories of hurricanes in this Saffir-Simpson scale:

- **Category 1:** hurricanes that have sustained winds of 74–95 miles per hour (119–153 km/h). These storms produce damage to unanchored mobile homes, shrubbery, and trees but no real damage to building structures.

Map of the world showing the areas of typical tropical storm generation and their typical paths. These storms have different names depending upon where they are generated, but they all have the same general characteristics.

- **Category 2:** hurricanes that have sustained winds of 96–110 miles per hour (154–177 km/h). These storms produce considerable damage to mobile homes, shrubbery, and trees with some trees blown down. There is also some damage to roofing material, doors, and windows of buildings as well as coastal flooding.
  - **Category 3:** hurricanes that have sustained winds of 111–130 miles per hour (178–209 km/h). These storms produce some structural damage to small residences and utility buildings with damage to shrubbery and trees, which are typically defoliated and commonly blown down. Mobile homes are destroyed. Coastal flooding may spread inland as much as eight miles (13 km) or more.
  - **Category 4:** hurricanes that have sustained winds of 131–155 miles per hour (210–249 km/h). These storms produce complete destruction of mobile homes with some complete roof structure failures on small residences and extensive damage to doors and windows. Areas lower than 10 feet (3 m) above sea level may be flooded, requiring evacuation of residential areas as far inland as six miles (10 km).
  - **Category 5:** hurricanes that have sustained winds greater than 155 mph (249 km/h). These massive storms produce complete roof failure on many residences and industrial buildings and some complete building failures with small utility buildings blown away. They also produce major damage to the lower floors of all structures less than 15 feet (4.6 m) above sea level and within 1,500 feet (462 m) of the shoreline. All residential areas on low ground within five to 10 miles (8–16 km) of the shoreline must be evacuated in most cases.
- The vast majority of hurricanes are category 1 storms with an exponential decrease in occurrence with increasing category numbers. In other words, category 5 storms are very rare. Hurricane production varies from year to year but was somewhat cyclical during the 20th century with some years producing many strong storms and others not producing many or any at all.

### HAZARDS OF HURRICANES

When hurricanes make landfall, there are several hazards that produce the damage. These hazards include high winds, storm surge, heavy rains, and tornadoes—these hurricane hazards lead to pollution and environmental damage.

**Illustration of a cutaway of a typical hurricane.** The graphical aspect shows the size (height and width) of the storm, and the illustration shows the anatomy of the storm including wind circulation patterns.

**Illustration of how storm surge impacts homes along coastal regions and how the storm surge height is calculated**

### High Winds

Hurricanes have very high wind speeds by definition. The highest wind speeds are those around the eye from about 25 miles (40 km) to 150 miles (240 km) outward from the center. The counterclockwise rotation coupled with forward movement results in a high-speed and a low-speed side of the hurricane. Most hurricanes move northward in the Northern Hemisphere. In this case, on the right side of the storm, the forward speed adds to the sustained wind speed to produce an increased wind speed relative to the average wind speed of the storm. On the left side of the storm, the forward momentum of the

storm decreases the wind speed by that amount. This effect is especially important in fast-moving storms. If a category 3 storm with wind speeds of 125 miles (200 km) per hour moves northward at 45 miles (72 km) per hour, the right side will have wind speeds of 170 miles (272 km) per hour while the left side has wind speeds of 80 miles (128 km) per hour. This means that in most cases, the right side is the dangerous side of the storm and all of the hazards are enhanced.

The high winds destroy buildings, storage facilities, and manufacturing plants. They destroy power lines and telecommunications service of all types

and can even damage other types of transmission and transportation lines if they are aboveground. They can overturn trucks and even railroad cars in some cases. It is these types of destruction that are most likely to cause chemical spills and related types of pollution on high ground.

They can also damage oil platforms and other distribution facilities. These structures are commonly out to sea or along the coast where the hurricane is still relatively strong. This strength means that the winds will still be at peak velocity. The damage will be compounded by the storm surge because it is driven primarily by the velocity of the wind.

### Storm Surge

The combined effect of the forward motion of a hurricane and the high wind speed forms a dome of water some 50–100 miles (80 to 160 km) wide on the surface of the ocean. This dome moves with the hurricane and strikes the coast as the storm surge. The height of the storm surge is typically included as part of the Saffir-Simpson scale. Category 1 storms have an estimated surge of 4–5 feet (1.2–1.5 m); category 2 is 6–8 feet (1.8–2.5 m); category 3 is 9–12 feet (2.8–3.7 m) above sea level; and category 4 is 13–18 feet (4–5.5 m) above. The highest is a category 5, which is more than 18 feet (5.5 m) above normal.

The reality is that the height of the storm surge striking land does not just depend upon the wind speed. It also depends upon the slope of the seafloor off the coast. A shallow drop-off means much more water able to be pushed into the storm surge, more bottoming out and rising up of the waves, and very little chance for water to escape from beneath, thus draining the dome. This produces larger storm surges. It also depends upon the shape of the coastline. Concave coastlines and harbors or bays focus the incoming waves to increase their height and speed. This is the same effect that increases the power of tsunamis. If the shoreline is convex, the waves will be dissipated because their energy is spread away. There are other factors such as tides and angle of incidence of the storm that also affect the storm surge that goes ashore. Certainly, the glancing blow of a hurricane traveling quickly northward along its left side will produce a much lower surge than a head-on landfall.

Storm surge produces heavy damage to all structures along the coast. The distance that the surge penetrates inland depends upon the topography of the coastal region. In flat areas, a strong storm surge may penetrate inland by a half-mile (0.8 km) or more. The strong waves flatten all but the strongest of structures and flood all others with salt water. All utility transmission lines are damaged or severed, and above-

ground chemical storage facilities may be washed off their footings. Refineries and oil production facilities located along the coast can be badly damaged or destroyed. The salt water, which may stand in puddles for several days or more, kills all but the hardiest of surviving plants and animals and deposits a layer of salt onto the soil, making it difficult to revegetate for years. The stagnant water may also breed disease, and it commonly ruins local water supplies.

### Heavy Rain

Hurricanes generate massive amounts of rain as they move ashore. The total rainfall depends upon the storm, but it is at least 6–12 inches (15–30 cm) and up to 40 inches (102 cm) depending upon conditions. The first factor depends on the size and intensity of the storm. Large storms with lower pressure carry more rain. Rains are generally heaviest with slower-moving storms because of longer periods of rain. The final main factor is topography. As air is driven up hill and mountain slopes, it tends to cool. The cooling causes increased condensation and heavier rain in a storm. This effect is called orographic precipitation. Certain areas are prone to this and suffer greatly if a hurricane pushes inland. Central America is such an area, where westward moving storms encounter the volcanic mountains of the western side. Hurricane Mitch, for example, dumped 40 inches (102 cm) of rain there, causing massive floods and mudslides and more than 11,000 deaths. The same effect occurs when storms move inland from the east coast of the United States. Rainfall totals increase dramatically as the storms move up the eastern slopes of the Appalachian Mountains, causing severe flooding primarily in North Carolina and Virginia.

Inland flooding has been the primary cause of tropical cyclone-related fatalities over the past 30 years. It can also cause tremendous environmental damage. Perhaps the most colorful of such events occurred when Hurricane Floyd struck North Carolina and flooded out the many lagoons of hog waste that had been located along the rivers. The hog waste floated down the rivers mixed with carcasses of drowned hogs. Less colorful but perhaps more dangerous are the washing out and overflowing of landfills, including Superfund sites. This is especially true in areas where hurricanes are uncommon and proper precautions have not been taken. The high water results in high fluid pressure on septic systems and sewers that can cause them to back up and spill onto the surface or into homes. Flood damage to buildings, chemical storage facilities, utility transmission lines, refineries, gas stations, and a number of other structures can cause spills and leaks.

**Block diagram illustrating orographic precipitation. As air is forced over an elevated area, it rises similarly to a low-pressure system and precipitation is produced. Once the air passes over the area, it carries less moisture and passes downward similarly to a high pressure that produces no precipitation.**

The result is a toxic soup of stagnant water mixed with pollutants and various diseases depending upon location.

### **Tornadoes**

The rain bands on a hurricane contain embedded thunderstorms, some of which can be severe. The severe ones can spawn tornadoes. They most commonly occur in the right-front quadrant of the hurricane, which is the high-wind-speed part. The more intense a hurricane is, the greater the tornado threat. These tornadoes usually develop within 150 miles (240 km) of the coast because the hurricane loses much of its intensity after moving inland.

Tornadoes can cause catastrophic disruption of utilities and damage to buildings, storage facilities, and essentially all permanent structures depending upon their strength. Pollutants can be readily discharged into the environment during a tornado. They can uproot trees and demolish whole forests,

upsetting local ecosystems for years to decades. The amount of debris generated by tornadoes is great and litters the landscapes of impacted areas for years.

These catastrophic effects of hurricanes are the main causes of environmental damage. Depending upon the area that is struck, the reports of releases to the U.S. Coast Guard, which handles them, can number in the dozens. Most of the releases are relatively small, but a few can be large, and, taken together, a significant amount of environmental pollution can result. After Hurricane Katrina in 2005, New Orleans was said to be awash with “toxic soup,” which is standing water that has been tainted with raw sewage and chemicals from the releases and allowed to ferment. There were 25 reported chemical releases of 50 barrels (2,600 gallons [9,880 L]) or more during this storm, all of which required remedial action. Hurricane Ike struck the Houston area in 2008 and generated 51 pollution reports, 15 of which required action. The more coastal development in the

**A New Orleans resident wades through oil-covered floodwaters in downtown New Orleans, Louisiana, after Hurricane Katrina, August 30, 2005. (AP Images)**

Southeast and the Gulf of Mexico, the more numerous and serious the pollution incidents will be in the wake of hurricanes. The possibility looms that a major environmental disaster could result from such a storm, especially if a large storm strikes an oil platform, oil refinery, nuclear power plant, toxic chemical depot, or any number of military installations.

### GLOBAL WARMING AND HURRICANES

The 2005 hurricane season was the worst in recorded history. It had the most storms, the most category 5 storms, and the most damage from storms ever in the United States. In particular, the devastating impacts of Hurricanes Katrina and Rita striking the same area within one month sent shock waves across the country. Proponents of global warming were quick to use this season as a warning to Americans that if the use of fossil fuel were not curtailed, this would be a common occurrence. There was a general panic among southern coastal residents as a result.

The theory that increased storms a result from global warming posits that increased air temperatures lead to increased ocean surface temperatures. If a larger region of the ocean has surface temperatures above 79°F (25°C), hurricanes will have a greater area to power up, thus becoming ever stronger. If warmer temperatures spread farther up the eastern seaboard, stronger hurricanes can strike farther northward in the Northeast, which is usually somewhat protected by the cooler ocean temperatures. Opponents of the increased storms theory have argued that the increased temperatures will also increase wind shear, strength of fronts, and other effects that degrade hurricanes.

The 2006 and 2007 seasons had few and weak hurricanes, and the panic faded away. The problem is that hurricane formation is cyclical. There are periods of many and intense hurricanes and periods of few and weak hurricanes. Even if hurricanes increase in number and intensity, they will not do so every year. There will just be more bad years and more dangerous storms over time. The global warming proponents may be correct in their predictions over the long term, but the short-term lack of results has cost them credibility.

# I

## **I-10 Truck Stop, Arizona Tonopah, Arizona 1997 Soil Pollution**

There is a truck stop and service area on I-10 westbound, about 50 miles (80.5 km) from Phoenix, at the intersection of Harquahala Valley Road in Tonopah, Arizona. As do many such facilities, this truck stop stored diesel fuel and gasoline in underground storage tanks (USTs). In 1997, as part of a U.S. Environmental Protection Agency (EPA) mandate, USTs at fuel storage facilities nationwide had to be upgraded or replaced. Facility operators decided to excavate and remove the old tanks and replace them with new ones. During that process, they found that some of the tank contents had leaked and contaminated the soil that surrounded the USTs. This contamination was in an area within five to 10 feet (1.5–3 m) of the surface and along the sidewalls of the tank excavation. Concentrations of total petroleum hydrocarbon (TPH) found in the soil ranged from 72 mg/kg to 26,000 mg/kg. The Arizona standard for TPH in soil was 100 mg/kg or less.

### **CLEANUP OF THE SITE**

The environmental consultant retained by the site owners to design an appropriate remedial solution for this release selected bioaugmentation as the most technically feasible and cost-effective way to address the soil that contained elevated levels of TPH. Bioaugmentation, also called microbe seeding, is a remedial technique that accelerates the bacterial degradation of organic compounds through the introduction of nonnative, specially cultivated, or even genetically engineered microbes into the subsurface to break down the contamination. In addition to trying to control or manage the “limiting conditions”

of bacterial growth including water, oxygen content, and pH, some remedial engineers supplement or augment the native bacterial population with microorganisms that are especially suited to degrading the contaminants of concern to speed the cleanup process. Researchers and companies develop these special bacteria basically in two ways. They attempt to duplicate a spill in a laboratory and then grow or cultivate bacteria that are most effective in remediating the contaminant. They also look at various bacteria and try to combine their best features into a single type by combining various deoxyribonucleic acid (DNA) strands.

At the I-10 site, the engineers began by drilling eight six-inch- (15.2-cm-) diameter boreholes about 12 feet (3.7 m) deep into the contaminated zone. Eight four-inch- (10.2-cm-) diameter perforated pipes then were installed in these boreholes. A mixture of 150 pounds (68.04 kg) of 20-20-20 fertilizer (20 percent nitrogen, 20 percent phosphate, and 20 percent potassium) and 4,200 gallons (15,899 L) of water was injected into the eight perforated pipes. Several weeks later, 330 gallons (1,249 L) of a proprietary microbial culture containing six types of bacteria and one type of yeast was mixed with 1,000 gallons (3,785 L) of water and pressure injected into the perforated pipes. At the same time, a sprinkler system was set up to keep the soil moist. A second injection was done about a month later, and, after 60 days of treatment, a round of soil samples was collected and tested for the presence of TPH. Laboratory results indicated that in the 11 samples tested, TPH levels had been reduced an average of 96 percent, with almost half the samples now containing TPH concentrations below the state cleanup standard.

Several conditions were present at this site that made bioaugmentation an appropriate remedial choice. The soil is predominantly a “clean” sand that does not contain much silt, clay, or organic material eroded from the surrounding volcanically formed mountains. The lack of significant organic matter tends to keep native bacterial populations low. Also, this part of Arizona is dry and hot, receiving about seven inches (17.8 cm) of rain per year with an average temperature of 70°F (21.1°C). The rain that reaches the ground tends to evaporate quickly. Low soil moisture is another factor that tends to limit the types and amounts of native bacterial populations.

Remedial engineers are still evaluating the need for and effectiveness of bioaugmentation. Proponents maintain that bioaugmentation is the best way to control the character of the biomass. The random mix of bacteria in the soil at a spill site is often not capable of fully remediating the release. Another advantage of matching selected bacteria to specific types of contaminants is that remediation time frames can be accelerated. There is no adjustment or adaptive period needed, so the non-native bacteria can begin degrading the contaminant immediately. This is especially important in time-sensitive applications, such as oil spills that might enter reservoirs or aquifers used as sources of drinking water.

Some scientists maintain that there is no clear evidence that these special bacteria do a better job than those already present in the soil. Opponents point out that the use of bioaugmentation includes the addition of large amounts of electron acceptors and nutrients, and native bacterial populations might just as well cause the contaminant-degrading effects. Also, because bacteria populations are so diverse, they are much better able to respond as contaminants degrade in the subsurface.

**imidacloprid** Albert Einstein is credited by some as having said that aside from nuclear war, the greatest challenge to human beings would occur if the bee populations were to be destroyed. Were that to occur, he predicted, humans would be able to survive as a species for a mere four years after this event. The thinking process behind this prediction is that bees do the vast percentage of pollination in the world and that without them plants would not be able to reproduce. Without vegetation, animals would die, and eventually humans would all die also. Whether Einstein actually made this claim or even had the interest or expertise to do so is debatable. This apocalyptic situation, however, actually began to happen at the beginning of the 21st century. Although the populations of wild bees had been steadily decreasing since the early 1970s, at this time, both wild and domestic bees suddenly began to disappear at an alarming rate. The direct cause was named colony collapse disorder (CCD), because entire colonies simply disappeared, rather than slowly weakening. Losses in some areas of the United States have been in excess of 90 percent, which is in the range of catastrophic, and all areas of the country have experienced significant losses of bee populations. It is estimated that in summer 2007, one-third of the remaining North American bees died off. The phenomenon has perplexed beekeepers and scientists alike and was blamed on a number of speculated causes from disease to parasites. These natural causes were probably wishful thinking by humans so as not to perceive themselves as the culprits. Recent studies suggest that this is likely not the case. New evidence suggests the direct cause may be the pesticide imidacloprid, and, as a result, it is in the process of being banned in several countries. Whether it is too late remains to be seen.

#### PROPERTIES, USES, AND PRODUCTION

Imidacloprid is a general use systemic chloronicotinyl insecticide that occurs as colorless crystals with a weak odor. It is available as dustable powder, granules, flowable slurry concentrate, suspension concentrate, soluble concentrate, and wettable powder. Commercially available products that contain

imidacloprid include Admire, Condifor, Gaucho, Premier, Premise, Provado, Winner, and Marathon. It is used to control sucking insects such as aphids, thrips, whiteflies, termites, turf insects, soil insects, and some beetles in agricultural applications. It kills insects through dermal contact and ingestion by selectively blocking neuronal pathways, causing buildup of acetylcholine, which leads to paralysis and death. Agricultural applications of imidacloprid are typically on rice, cereal grains, maize, potatoes, vegetables, sugar beets, fruit, cotton, hops, and turf. It is also effective against fleas and is used on pets and some livestock.

Imidacloprid is a relatively new pesticide that was developed after many of the traditional pesticides had been banned. Bayer CropScience introduced imidacloprid in 1991 and registered it for use in the United States in 1994. Since then, it has become extremely popular, becoming Bayer CropScience's leading product because its formulation makes it deadly to insects but far less toxic to mammals and humans. It is now one of the most widely employed pesticides, used in more than 120 countries worldwide on more than 140 agricultural crops.

### ENVIRONMENTAL RELEASE AND FATE

As with any other pesticide, imidacloprid is primarily released as a nonpoint source pollutant with minimal accidental point source releases from manufacturing, transportation, and storage. It does not evaporate readily and appears not to be transported easily from areas of application. It is also readily degraded by photolysis, and, as a result, it is not considered to be a problem in air. The main medium of concern is soil. Imidacloprid binds moderately to soil in the top few inches but less so in deeper horizons. The removal half-life varies widely depending upon soil type, fertilizers, and ground cover. The most commonly reported dissipation half-life is 26.5–48 to 190 or 229 days under field conditions, although it has persisted for an astonishing 997 days under aerobic laboratory conditions with breakdown through chemical reactions. It apparently is removed more quickly if there is a soil cover, such as in turf (dissipation in 21–33 days), and much more slowly in agricultural or fallow fields (one to two years), especially if it contains natural fertilizer such as manure or is at higher pH. Leaching of imidacloprid into groundwater is considered to be slow and minimal, although it has been found in well water in several places, including New York and Colorado. Leaching appears to be quicker in sandy soils and inhibited in organic-rich soils. Hydrolytic removal half-life in groundwater has been reported

to be 30–44 days at neutral pH and much quicker under very basic conditions ( $\text{pH} > 11$ ). Breakdown of imidacloprid in surface water has been reported to range from three hours to 14 days with breakdown by exposure to sunlight (still water) to much longer than 31 days with increasing times under neutral to slightly basic conditions and turbulent conditions. It has been found in surface waters in both New York and Florida.

Imidacloprid is toxic to upland game birds as well as ducks and others, but it was found that most birds would simply avoid coated seeds after experiencing gastrointestinal distress and loss of coordination after ingesting them. It is considered to be of moderately low toxicity to fish but very high toxicity to aquatic invertebrates. It is not very toxic to mammals. Imidacloprid is highly toxic to bees, wasps, and hornets, especially if it is applied during plant flowering. In the past, it was not considered to be hazardous when used as a seed treatment. Plants, however, readily take up even the smallest amounts of imidacloprid residues and distribute them throughout their structures including into the pollen. The new information on its persistence in soils suggests that even seed treatments may be dangerous. In addition to reduced activity, one of the main effects on bees is to disorient them. It is thought that many simply cannot return to the hive. There are many other symptoms that are appearing with CCD, including catastrophic breakdown of the bees' immune system. It is still hotly debated whether imidacloprid is the lone culprit in CCD or even a contributor. Several of the metabolites of imidacloprid are even more toxic than the parent.

### HEALTH EFFECTS FROM EXPOSURE

The U.S. Environmental Protection Agency (EPA) classifies imidacloprid in toxicity class II, which is moderate, and in class III among pesticides (scale is I–IV). Acute exposure to imidacloprid causes fatigue, apathy, muscle twitching, cramps and weakness, loss of coordination, and labored breathing. It may cause coma and death in extremely high doses. Chronic exposure at high dosage has been shown to produce thyroid lesions, weight loss, irritation of the liver, and retinal damage. Exposure of pregnant laboratory animals resulted in decreased weight of newborns and some skeletal abnormalities. The EPA classifies imidacloprid as a group E carcinogen, which is the lowest for those substances where there is evidence of noncarcinogenicity for humans. It is also only weakly mutagenic to a few cell types in laboratory tests, including human cells.

### REGULATIONS ON HUMAN EXPOSURE

The frightening part of the problem with imidacloprid is that it is not regulated by any federal agencies because it is not particularly toxic to humans. The EPA does not regulate it except in requiring labeling. The only place where the use of imidacloprid has even been restricted is France, where beekeepers convinced the government to ban its use on sunflowers after suffering heavy losses of bees beginning in 1997. The restrictions have continued, but, because the ban does not extend to any other crops and the replacements are also toxic to bees, the damage to bees has not abated. A similar legal battle is now taking place in Nova Scotia, Canada, where imidacloprid use on potatoes is being blamed for severe bee losses and consequent devastation of their blueberry crops. To date, nothing has been done to stop the problem, primarily because it is not proven that imidacloprid is the actual culprit for CCD.

**impacts, extraterrestrial** Although they are very rare, impacts of large extraterrestrial objects with the Earth can cause the most apocalyptic of environmental disasters. Prior to the 1970s, no one

even considered large extraterrestrial impacts to be in the realm of possibility. Then, a geologist named Walter Alvarez set out to determine the cause of the extinction of the dinosaurs and many other marine and terrestrial organisms at the Cretaceous-Tertiary boundary, about 65 million years ago. He went around the world studying sedimentary strata that record this period. With his Nobel Prize laureate father, the physicist Luis Alvarez, he proposed that all the data pointed to an extraterrestrial impact at the boundary. This announcement caused a revolution in geology, and, for the next two decades, scientists would amass a compelling collection of data supporting the impact. A crater would even be identified off the north coast of the Yucatán Peninsula in the Gulf of Mexico, called Chicxulub. Evidence of many other large impacts around the world would also be discovered, and suddenly the impossibility became a probability.

The occurrence of impacts should really not be surprising. The building of the planets from a rotating mass of nebular debris was based upon impacts. The plate tectonic and weathering systems of the Earth have removed all of the evidence of this early history. Mercury and the Earth's Moon, however, among other bodies, preserve extensive evidence that planetary bodies were accreted from tens of thousands of major impacts to achieve their size. These early impacts were large enough to knock large pieces off already formed planets. A popular theory is that the Moon was actually once part of the Earth but was removed as the result of a large impact. More recently, meteorites on Earth were found to have Martian affinities. It was hypothesized that a large impact on Mars may have ejected material high enough to escape the gravitational grip of the planet and that that material subsequently collided with Earth.

Not all scientists were surprised by Alvarez's revelations. Eugene Schumacher studied the Barringer crater (also known as Meteor Crater) in Arizona and fully described the process by which large extraterrestrial bodies impacted the Earth. He was the chief geological instructor for the National Aeronautic and Space Administration's (NASA's) Apollo program, which instructed astronauts how to negotiate craters and how to sample the rocks during lunar landings. Later, initially on his own, he began a program to search for extraterrestrial bodies that could impact the Earth. One of the discoveries that he made during this research was that a large comet appeared to be headed toward Jupiter. As the comet entered the atmosphere, it broke into a number of pieces. Soon after, in July 1994, humans had visual evidence that large bodies could still impact planets,

**Meteor Crater in Arizona** (François Gohier/Photo Researchers, Inc.)

as the pieces of the Schumacher-Levy 9 comet collided with Jupiter. The impacts were catastrophic to Jupiter, and scars in its atmosphere were visible for 14 months afterward. Although Jupiter is a much larger planet than Earth with a much larger gravitational field to capture space bodies, the impact caused humans to take notice and devote more effort to scanning the skies for extraterrestrial objects. Several disaster movies featuring asteroids colliding with Earth were released after the event as well.

### EXTRATERRESTRIAL BODIES

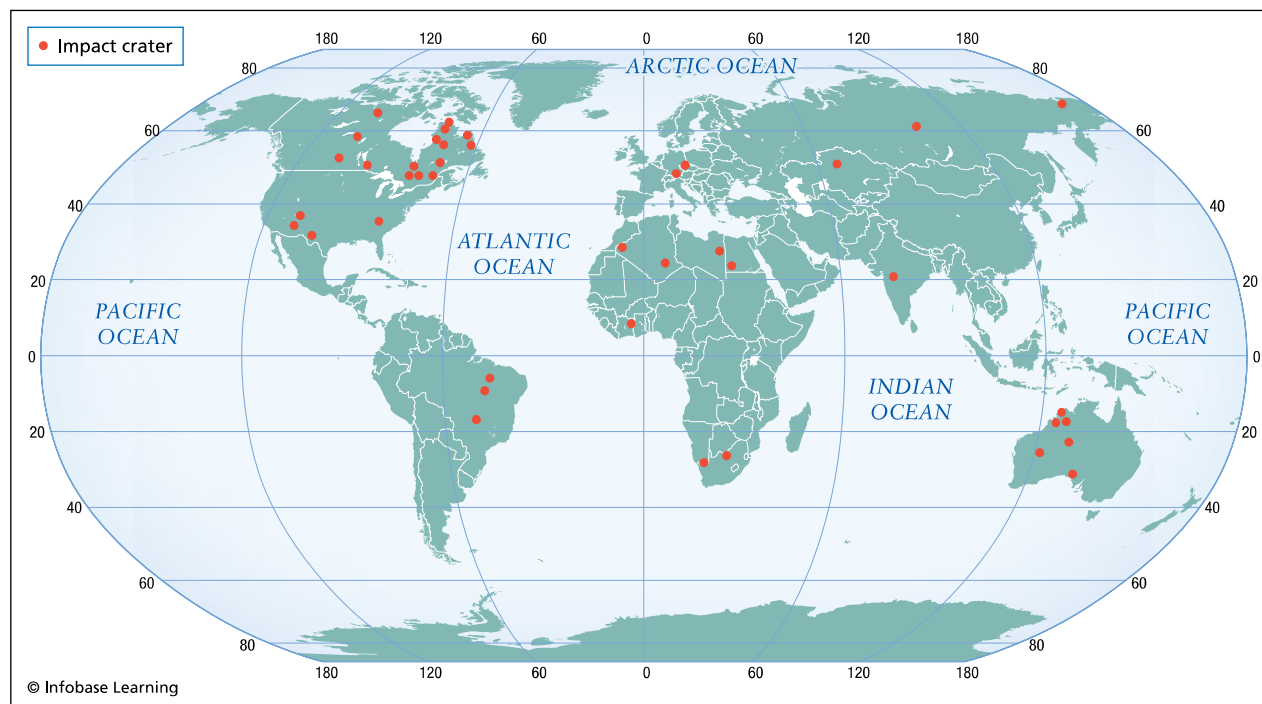

There are several types of extraterrestrial bodies that could collide with the Earth classified by size and composition. The largest of the dense bodies is an asteroid. There is a belt of asteroids between Mars and Jupiter that forms a ring around the Sun. Apparently the solar system looked similar to Saturn at one point in its development, and the rings provided the material for accretion of the planets. Asteroids range from 33 feet (10 m) to 621 miles (1,000 km) and are stony and carbonaceous (C-type), metallic (M-type), or some mix of the two (S-type), though there is evidence that some are ice bearing. There

are approximately 700,000–1.7 million asteroids with a diameter of 0.6 mile (1 km) or more in the asteroid belt. The largest asteroid by far is Ceres, which should really be classified as a planetoid. At 578 miles (933 km) across and containing about 25 percent of the mass of all the asteroids combined, it is nearly twice as large as the second biggest asteroid. The next largest are Pallas, Vesta, and Hygiea, which range from 248 to 325 miles (400 to 525 km) in diameter and with Ceres constitute nearly 50 percent of the total mass of the belt. All other asteroids in the belt are less than 210 miles (340 km) across.

Several of the asteroids have orbits relatively close to Earth. Collisions among asteroids are relatively common, with the potential to knock them out of their orbit and send them into the path of other planets. Asteroids are strongly affected by the gravity of Jupiter. Any perturbations in its gravity field, even in regular variations, can also dislodge an asteroid from the belt. Asteroid impacts with the Earth are, by far, the most dangerous of all extraterrestrial impacts.

The next largest of the extraterrestrial bodies is the comet. Comets range from less than 10 feet (3 m) to more than 124 miles (198 km) in diameter. They

**Map of the Earth showing the locations of large impact craters—more than 200 have been identified.**

are generally dirty snowballs, composed primarily of ice with rock and metal debris mixed in, although some are thought to have stony cores. Comets originate either at the edge of the solar system in the Kuiper belt or far out of the solar system in the Oort cloud. Some comets break free of these areas of origin and begin making huge orbits around the Sun. Halley's Comet, the most famous of the orbiters, appears every 77 years, the time of its orbit around the Sun. As comets move closer to the Sun, they begin to melt and develop a tail of gases and debris. The comet itself is the nucleus.

Extraterrestrial bodies less than 32 feet (10 m) that are not composed of ice are meteoroids. Like asteroids, they are classified on the basis of composition as stony, metallic, or carbonaceous. Stony meteorites are chondrites and composed largely of iron and magnesium silicates. Metallic meteorites are iron and/or nickel, and carbonaceous meteorites are stony meteorites with a high carbon content. The term *meteorite* refers to a meteoroid that landed on the Earth and can be studied; it is a "shooting star," or extraterrestrial body that shines as it burns up in the Earth's atmosphere.

### ENVIRONMENTAL IMPACT

When an extraterrestrial body enters the Earth's atmosphere, it is traveling at velocities of 27,000–161,000 miles (43,200–257,600 km) per hour. At

this speed, friction with the molecules in the atmosphere causes them to heat up. In the oxygen-rich atmosphere, smaller bodies tend to burn up before they reach the ground. Comets and friable carbonaceous bodies may even explode in an aerial airburst. The most famous of these events was the Tunguska event in Siberia. On June 30, 1908, at 7 A.M., a fireball exploded with the force of 10 megatons of trinitrotoluene (TNT) or 10 hydrogen bombs about 23,000 feet (7 km) above the remote Tunguska River valley. The explosion flattened and burned 770 square miles (2,000 km<sup>2</sup>) of forest, and the noise was heard over an area of 386,000 square miles (1 million km<sup>2</sup>). It is estimated that the body was a small friable asteroid about 80–160 feet (25–50 m) in diameter and traveling at a speed of more than 50,000 miles (80,000 km) per hour. If such an explosion happens over a city, tens of thousands of people or more will be killed.

When the Chicxulub impact became a possibility in the late 1970s, the U.S. Congress held hearings on the potential environmental damage of such a disaster. Such dignitaries as Carl Sagan were included in the group. The new phrase introduced at this time was "nuclear winter," which described the effect of both a nuclear war and an asteroid impact. A large collision would pulverize the asteroid, and a huge amount of rock and soil at the impact site, and raise a huge dust cloud high into the atmosphere. The particulate from such an event would encircle the

**Map of the Gulf of Mexico and surroundings showing the location of the Chicxulub Crater on the Yucatán Peninsula, Mexico. The impact that formed this crater is believed to have caused the mass extinction at the Cretaceous-Tertiary boundary.**

planet, drastically reducing sunlight for periods up to several years. Not only is the particulate dangerous to most life on the planet through inhalation and poisoning, the lack of sunlight would eliminate photosynthesis and cause a worldwide famine.

The “smoking gun” evidence for the Chicxulub impact according to Luis Alvarez was the layer enriched in iridium. He noted that iridium is uncommon at the Earth’s well-evolved surface but much more abundant in primitive bodies such as asteroids. Although iridium has not been identified as particularly dangerous, especially in such small quantities, other elements and inorganic compounds common in primitive bodies are. Nickel is quite common in asteroids and meteoroids and is an environmental pollutant. Chromium may also be present in some meteoroids, as may titanium and other metals. In the area around the impact crater, these pollutants may be at concentrations of environmental concern, even up to minable levels. Further, the high heat and pressure at the impact may be so intense that glass fragments fine enough to cause silicosis may be abundant. Other compounds that may also be undesirable may be created.

**indoor air pollution** Although the common perception is that houses and buildings are clean and outdoors is dirty and potentially disease-ridden, the reality is that, in the vast majority of cases, indoor air is far more dangerous. Vast numbers of pollutants can occur indoors from a variety of sources. Symptoms of this pollution can vary from mild to severe, even resulting in terminal diseases such as cancer and death, both from long- and short-term exposure. The World Health Organization released a report in 1984 that found up to 30 percent of new and remodeled buildings generate excessive health problems. One reflection of this is sick building syndrome (SBS), a nonspecific problem in which a large percentage of people become ill within a specific building. There can be a number of causes for SBS, and all of them are some form of indoor pollution.

Although the actual number of chemicals and other components of indoor air pollution can number in the thousands, the vast majority are in negligible concentrations. Most also fall into relatively few source categories including home combustion devices/appliances, environmental tobacco smoke (ETS), volatile organic compounds (VOCs), heavy metals, biological sources, radiation, and miscellaneous sources. Home combustion includes any indoor device that burns natural gas, kerosene, wood, or oil such as gas stoves, fireplaces, gas dryers, some space heaters, and even some furnaces and water heaters, depending upon the device and conditions. ETS carries more than 4,000 chemicals that overlap many of the other categories and is by far the most dangerous of the nonbiological pollutants. VOCs can have numerous direct sources, ranging from numerous cleaners, paints, and hobbies to indirect sources such as the evaporation of plastics and even tobacco smoke. There are numerous biological sources, ranging from pet dander

to molds and fungi in moist areas to viruses and bacteria to live pests such as dust mites.

### COMBUSTION BY-PRODUCTS

Although many environmentalists would rather use natural gas in their homes because it is far more efficient than electricity, there can be more severe problems caused by indoor air pollution. This applies to furnaces, space heaters, stoves, water heaters, and dryers. The same issues arise from oil burning furnaces and water heaters, kerosene space heaters, fireplaces and woodstoves, gas lamps, and grills. The problem is that oxygen is used in combustion, and in many cases the dwelling is progressively deprived of oxygen. The by-products of burning may also be dangerous, especially if the appliance runs on too little oxygen. Partially burned hydrocarbons and oxygen-poor combustion by-products are especially dangerous to health. Although there are many compounds that fall into this category, the most common indoor pollutants that are combustion by-products are carbon monoxide, nitrogen dioxide, and sulfur dioxide. These compounds tend to occur together in many instances and produce a combination of symptoms including dizziness or headache, confusion, nausea, fatigue, eye irritation, upper respiratory irritation, wheezing and bronchial constriction, persistent cough, increased respiratory infections, and worsening of symptoms in people who have chronic circulatory, cardiovascular, and respiratory conditions (chronic obstructive pulmonary disease [COPD]). Individually, these by-products have specific indications.

#### Carbon Monoxide

Complete burning of hydrocarbons and other combustion products produces carbon dioxide. If carbon dioxide displaces too much oxygen, a person can suffocate, but this is a rare occurrence. If burning is incomplete because of lack of oxygen, carbon monoxide is produced in its place depending upon the degree of oxygen depletion. This situation is common when burning takes place in an enclosure. Carbon monoxide is a colorless, odorless gas that acts as an asphyxiant. Rather than simply displacing oxygen, it actually participates in respiration and combines with hemoglobin in the blood to form carboxyhemoglobin (COHb), thereby disrupting oxygen transport and respiration. This deficiency affects the areas of the body most in need of oxygen first, including the brain and large active muscles. Symptoms include fatigue, headache, dizziness, nausea, vomiting, confusion, and tachycardia depending upon COHb in the blood.

All these symptoms can be mistaken for influenza. By the time headache, fatigue, and impaired judgment appear, the COHb is typically at 30 percent and confusion at 40 percent. At 60 percent COHb, victims will lose consciousness and expire if they are not removed from the area in a timely manner. Death comes at lower concentrations and more quickly to people with chronic circulatory, cardiovascular, or respiratory conditions (COPD). It is this rapid onset of death that has made carbon monoxide poisoning a common choice for suicide, which is typically accomplished by sitting in a running automobile in a closed garage.

Carbon monoxide poisoning is not uncommon in homes and is especially prevalent in winter months. Faulty and malfunctioning furnaces, poorly ventilated space heaters, and leaking chimney flues are common culprits in such cases. Weather can also contribute to carbon monoxide poisoning. Under certain conditions of rising pressure in a calm system like that which might be encountered in winter or if wind conditions are ideal, furnace exhaust can be forced back down the chimney and into the house. Many deaths and serious injuries have resulted from these events. For this reason, many areas require carbon monoxide detectors in homes. Newer furnaces are much more efficient, produce very little carbon monoxide, and have exhaust systems that are not prone to weather fluctuations, so, in time, accidental carbon monoxide poisoning should become less common. In historical times, when all heating and lighting were done with combustion appliances, low-level carbon monoxide poisoning was far more common. Houses, on the other hand, were drafty and not well sealed, and, as a result, death from carbon monoxide poisoning was not as common as one would expect.

#### Nitrogen Dioxide

Nitrogen dioxide is an indoor pollutant from combustion. It is relatively insoluble in water and is, therefore, not terribly irritating to the eyes and upper respiratory tract, although there can be some reaction particularly among sensitive people. It is, however, irritating to the lower respiratory tract. Exposure can cause increased reactivity in asthmatics; decreased lung function in people who have respiratory diseases; increased risk of respiratory infections, especially in children; and even pulmonary edema and possible death at high concentrations. It has also been shown to contribute to the development of acute or chronic bronchitis. Typically, concentrations of nitrogen dioxide are relatively low in indoor air and readily removed when the combustion source is addressed. Outdoor air

typically has twice as much nitrogen dioxide as indoor air.

### **Sulfur Dioxide**

Sulfur dioxide is another indoor pollutant from combustion. Unlike nitrogen dioxide, it is relatively soluble in water and is, therefore, highly irritating to the eyes and upper respiratory tract in concentrations as low as six parts per million (ppm). Sulfur dioxide reacts with the moisture in the mucosa of the eyes, nose, and throat, producing sulfuric acid, which burns these areas. It can also cause acute bronchial constriction in people who have asthma or as a hypersensitivity reaction in others at concentrations as low as 0.4 ppm. Long-term exposure to sulfur dioxide can contribute to chronic lung disease and decreased lung pulmonary function. Typically, concentrations of sulfur dioxide are relatively low in indoor air and readily removed when the combustion source is addressed.

### **ENVIRONMENTAL TOBACCO SMOKE (ETS)**

The U.S. Environmental Protection Agency (EPA) estimates that some 38,000 people die per year of diseases resulting from exposure to ETS including 3,000 of lung cancer. ETS produces as many as 300,000 lower respiratory tract infections per year in children younger than 18 months old. Tobacco smoke is a complex mixture of numerous chemical compounds. Approximately 4,000 chemical compounds have been identified of the estimated 100,000 total in tobacco smoke. These 4,000 compounds, however, represent 95 percent of the total mass and include more than 50 known carcinogens and up to 400 toxins. Hazardous compounds in tobacco smoke include tar, arsenic, lead, cadmium, nickel, carbon monoxide, carbon dioxide, nitrogen oxides, hydrogen cyanide, benzene, ethylbenzene, vinyl chloride, dioxin, polycyclic aromatic hydrocarbon (PAH) including benzopyrene, volatile and nonvolatile aldehydes and ketones, hydrazine, quinones, butadiene, radioactive polonium, ammonia, N- and other nitrosamines, phenols, alcohol, carboxylic acid, formaldehyde, nicotine, sulfur dioxide, and various pesticides and fertilizers. There are two types of tobacco smoke that constitute much of ETS, mainstream, which is inhaled directly into the lungs, and sidestream, from smoldering cigarettes. Sidestream smoke results in incomplete burning of tobacco, which produces carbon monoxide, as well as 40–170 times the ammonia content of mainstream smoke, four to 10 times the content of nitrogen oxides, 10 times the benzene content, six to 100 times the N- and other nitrosamines, and 30 times the aniline.

Key symptoms of exposure to ETS in adults include nasal congestion, persistent cough, irritated eyes, headache, wheezing and bronchial constriction, sinus inflammation, and exacerbation of any chronic respiratory conditions. Key symptoms in children include onset of asthma, increased severity of asthma, frequent upper respiratory infections, persistent middle ear problems, snoring, and repeated bronchitis and pneumonia. These symptoms can vary from mild to severe, depending on the amount of smoking (exposure) relative to the size of the dwelling and the sensitivity of the individuals. The primary cause of these overt symptoms is the coarse particulate (particulate matter with a diameter of 10 microns or less [PM10]), whereas the chemicals and fine particulate typically cause the problems of long-term exposure such as heart disease, stroke, cancer, blood clots, and eye problems. Although there are filtering systems available that can remove the particulate and many of the chemicals, the best solution is not to allow smoking in the dwelling.

### **BIOLOGICAL AIR POLLUTANTS**

There are biological pollutants of some sort in virtually all buildings in varying degrees. It is only when these pollutants are dangerous to the occupants that they become enough of a problem that they must be addressed. Sources for these pollutants vary from viruses and bacteria on the human occupants; animal occupants including pets, insects, and vermin that shed allergens; moist areas that spawn bacteria and fungi; to influx of outdoor air and all of the biota contained within. Moist and wet areas are of special concern because they can host a large number of dangerous pollutants. Kitchens, bathrooms, basements, washing rooms, humidifiers and dehumidifiers, and certain heating, ventilation, and air-conditioning (HVAC) systems are the most common sources of microbial activity and dust mites, among others, but even wet carpets and towels can harbor problems.

There are three types of human diseases that can result from biological pollutants in indoor air: infections, hypersensitivity disease, and toxicosis. Infections result when airborne pathogens from known or unknown diseases infect human tissue. Depending on the pathogen, they can range from mild to severe and even fatal in rare cases. Hypersensitivity diseases involve the reaction of the immune system to a specific airborne irritant to which individuals are particularly sensitive. In toxicosis, toxins are produced by biological processes and released to the air, where they can affect humans in a range of ways. The key symptoms of exposure to biological indoor air pollution are vari-

able depending upon the source and type but commonly include cough, tightness of the chest, runny nose, irritated eyes, recurrent low-grade fever, malaise, exacerbation of asthma, and symptoms specific to a particular disease. The following are symptoms and sources of specific diseases.

### **Tuberculosis**

Tuberculosis (TB) is a severe degenerative disease of the lungs that is commonly transmitted through the air. It is more common in overcrowded areas with inadequate ventilation. The symptoms include cough, shortness of breath, fever, and fatigue that worsen with time, ultimately leading to death if not treated. TB was steadily declining from its first monitoring in 1953 until the mid-1980s, when it began to rise sharply. In part, this increase resulted from the expanding acquired immunodeficiency syndrome (AIDS) epidemic, the victims of which are particularly susceptible to TB. The increase in TB during this time also corresponded to increased immigration into the United States, including by people who had contracted the disease in their home country. TB germs can be carried by a person without his or her ever contracting the disease. It is estimated that about 10 million Americans are infected with TB germs, of whom only about 10 percent will develop TB disease in their lifetime. The remaining 90 percent will never get sick from TB or be able to spread it to other people. On a worldwide scale, it is estimated that nearly 1 billion people will become newly infected, more than 150 million will become sick, and 36 million will die between now and 2020.

### **Legionnaires' Disease**

Legionnaires' disease became well known in 1976 when an outbreak of "unexplained pneumonia" sent numerous people attending a convention of the American Legion in Philadelphia, Pennsylvania, to the hospital. A number of the people died, and this apparently new disease, appearing in the media on a daily basis, panicked Americans. It was, in fact, simply a more virulent version of Pontiac fever, a flu-like illness that was identified in Pontiac, Michigan, in 1968. Legionnaires' disease is a pneumonia that is much more common in individuals more than 50 years old and especially in those who smoke, drink to excess, or have problems with their immune system. The fatality rate is among the highest for those diseases caused by indoor air pollution at 5–25 percent, and death results relatively quickly. The case in Philadelphia was caused by the bacteria growing in a cooling tower, but it has been found in HVAC systems, whirlpool baths, humidifiers, vegetable mis-

ters, and even fountains and home water taps, in some cases. Between 8,000 and 18,000 people are hospitalized each year with Legionnaires' disease in the United States, but many more cases are not reported because they are misdiagnosed as influenza.

### **Allergic Reactions**

Allergic reactions in sensitive people are, by far, the major concern with regard to biological air pollutants. Allergens that trigger allergic reactions primarily arise from pet dander; house dust mites; other insects such as cockroaches, ants, and flies; mold and mildew; plants and flowers; and bacterial enzymes, algae, and furnishings that contain allergen-bearing materials such as feathers and fur. Allergens may also enter a home from outdoor air. Symptoms of allergic reactions may include runny nose, congestion, postnasal drainage, irritated eyes, labored breathing and asthma, and, in some cases, hives. Most of these symptoms are simply annoying, but asthma can be deadly and must be closely monitored. Dust mites can infest homes not only in HVAC systems but also in bedding and carpets.

### **Hypersensitivity Pneumonitis**

Otherwise known as allergic alveolitis, hypersensitivity pneumonitis is an interstitial lung disease that is caused by exposure to airborne antigens. It is serious enough that it can lead to end-stage pulmonary fibrosis. Normally, it is restricted to farmers and pigeon breeders, affecting 1–5 percent of that population, but it has also been found as outbreaks in office buildings with mold and bacteria contamination in their air-conditioning and humidifier systems. It can also occur in homes with contaminated HVAC systems and humidifiers or with pet birds. It can take years for a person to develop sensitivity to the causes of this condition, but, thereafter, he or she may experience symptoms including cough, dyspnea, chills, myalgia, fatigue, high fever, lung nodules, and an elevated white blood cell count.

### **Humidifier Fever**

Humidifier fever is similar to hypersensitivity pneumonitis in its symptoms but has a high attack rate and short-term effects that are indicative of toxins. It appears to be related to exposure to amoebae, bacteria, or fungi found in humidifiers, air conditioners, and aquariums. Symptoms appear within a few hours of exposure and include fever, headache, chills, myalgia, and malaise. They typically subside within 24 hours. The number of people affected during a given outbreak can be quite high, exceeding 25 percent of those exposed in some cases.

### Mycotoxins

Mycotoxins are fungal metabolites in indoor air that result from fungal colonies established in moist areas. Most mycotoxins are ingested in contaminated foods, but they can be present in airborne spores. The range of symptoms from exposure to mycotoxins is broad, from temporary and minor irritation including dermatitis to suppression of the immune system and even cancer.

### VOLATILE ORGANIC COMPOUNDS (VOCs)

VOCs have received much publicity concerning their potential adverse health effects, and, as a result, many common products have been reformulated to reduce or eliminate their VOC content. Nonetheless, they are still very common in household uses, and daily exposure is common. VOCs evaporate readily whether they are solids or the more common liquids. They include numerous chemicals such as benzene, formaldehyde, acetone, petroleum products and components, perchloroethylene, toluene, xylene, ethylbenzene, 1,3-butadiene, polyvinyl chloride, chloroform, and literally hundreds of others. They are found in all kinds of commonly used products such as paints and lacquers, paint strippers, cleaning supplies, pesticides, building materials and furnishings, office equipment such as copiers and printers, correction fluids and carbonless copy paper, graphics and craft materials including glues and adhesives, permanent markers, and photographic solutions. Other household products that include VOCs are varnishes, solvents, wax, and many cleaning, disinfecting, cosmetic (hairspray, nail polish, and perfume), degreasing, and hobby products. They evaporate out of many plastic and vinyl products including carpeting and automobile upholstery. In fact, amounts of organic pollutants are typically two to five times higher in homes, cars, and offices than in outside air, regardless of whether they are located in rural or highly industrial areas.

VOCs produce a variety of symptoms ranging from mild to severe. Typical symptoms include dizziness, lightheadedness, fatigue, and headache; nose, throat, and eye irritation; and nausea, dyspnea, skin irritation in some cases, and a general decline in serum cholinesterase levels. High levels of some VOCs can result in intoxication, and, for that reason, they are used in huffing by substance abusers. Some VOCs such as benzene, xylene, and toluene are documented carcinogens and should be avoided. Some of the most notorious VOCs are formaldehyde and components of pesticides.

### Formaldehyde

Formaldehyde is classified as a probable human carcinogen by a number of regulatory agencies. It was used extensively in new house construction and renovation in the form of urea-formaldehyde foam insulation (UFFI) until the early 1980s, when it was found to be harmful. Now it is seldom used, but formaldehyde is still present in resin used in some finishes, plywood, paneling, fiberboard, and particleboard that is commonly used for building materials, components of furniture and cabinets, permanent-press fabric, draperies, and mattress ticking. As a result, most people are exposed to formaldehyde vapors on a daily to weekly basis. The most recent publicized case of formaldehyde as an indoor air pollutant was in the homes provided to the refugees from the 2005 Hurricane Katrina disaster by the Federal Emergency Management Agency (FEMA). Less than a year later, indoor formaldehyde levels in these homes were found to be above the acceptable limits.

Symptoms of exposure to formaldehyde vary from slight irritation of the eyes, nose, and throat to tightness of the throat and chest accompanied by wheezing. The more serious reactions to formaldehyde exposure may reflect hypersensitivity. It is estimated that between 10 and 20 percent of the U.S. population, including the majority of asthmatics, are hypersensitive to formaldehyde. Long-term exposure to formaldehyde greatly increases the risk of developing certain cancers.

### Pesticides

Although pesticides can fall into a number of categories of pollution, especially because they carry poison, a significant amount of VOC is released with the use of foggers and pest strips. The propellant in sprays and foggers is primarily VOC. Symptoms of exposure may include headache, dizziness, muscular weakness, and nausea, and they may be exacerbated by exposure to the poison in the pesticide.

### HEAVY METALS

There are several types of inorganic, heavy metal pollutants that can be contained in indoor air. By far, the most common and dangerous of these are lead and mercury. Most others, introduced from burning and primarily from tobacco and fireplaces or from outdoor air in rare instances, occur in extremely low concentrations. Other sources such as machine shops, garages, and fireworks displays are very specific and not common to many houses. Lead and mercury exposure have different sources and symptoms than most other metals.

### Lead

Lead has been one of the great boons and, at the same time, scourges of human civilization. It has been readily usable for a huge variety of purposes for which safe replacements have been difficult to adapt once lead was found to cause a health problem. For the past 30 years, lead has been banned from numerous common consumer applications, and yet it is still a major health concern. The main areas of concern are lead in old pipes; lead in paint, hobbies, and crafts; and lead in consumer items from other countries. Lead in paint is clearly the most important source for general indoor air pollution, although specific activities that use lead directly can yield more severe problems. In 2004, the U.S. Department of Housing and Urban Development (HUD) estimated that about 38 million homes in the United States contain some lead paint. Of these, some 24 million homes, or about 25 percent of the total, contain significant deteriorating lead paint or lead-contaminated dust. In 2002, there were still more than 310,000 children below the age of six in the United States who had too much lead in their blood, and paint dust was the main culprit. It is also estimated that many fetuses are exposed to lead in vitro.

Symptoms of lead poisoning in adults include gastrointestinal problems ranging from distress, constipation, and nausea to anorexia, fatigue, muscle weakness and tremors, personality changes, headache, hearing loss, and loss of coordination. In small children and infants, symptoms include irritability, abdominal pain, hyperactivity, short attention span, learning disorders, and, in some cases, seizures and loss of consciousness. The primary health problems are caused by long-term, low-level lead exposure, rather than acute exposure. Lead builds up in the body and has a cumulative negative effect on concentration, learning ability, and general intelligence. These long-term symptoms can be unnoticed for a long period to the point where the damage is severe and permanent.

### Mercury

Mercury is a heavy metal that was a problem in indoor air largely because lead was reduced or eliminated from paint. When lead was discovered to be the health threat that it is, the trend toward using latex paint as an alternative to oil paint increased. Many latex paints contained phenylmercuric acetate (PMA), a preservative that was a source of mercury vapor in indoor air during application and drying. As a result of increased adverse health effects, PMA was restricted to exterior paints in 1990 and banned

from all paints in 1991. Through continuing legislative efforts, mercury has largely been eliminated from most household items such as thermometers and batteries, but it may still be found in some older items. It is also still used in mercury vapor lamps for exterior lighting and some automatic switches.

Symptoms of exposure to mercury in indoor air are headache, intermittent fever, muscle cramps and tremors, tachycardia, acrodynia, personality change, and neurological dysfunction. It is these last two symptoms for which mercury exposure is most noted. Wool felt for hats used to be processed with mercury. This is the reason that the Hatter in the book *Alice in Wonderland* was mad.

### RADIATION AND ELECTROMAGNETIC (EM) FIELDS

Households are awash with EM fields and radiation. For this description, EM radiation is considered to be ionizing (X-rays, ultraviolet [UV] radiation, gamma radiation), whereas EM fields are considered to be nonionizing (electric and magnetic fields). Every appliance gives off an EM field. The strength of the field varies with the amount of electric current passed through it. Studies have suggested a link between exposure to low-frequency EM fields and onset of childhood leukemia. The rate of leukemia in children is so low and the correlation so weak, however, that the effect is still debatable. Nonetheless, there is a potential for damage from long-term, symptom-free exposure to strong EM fields.

Ionizing EM radiation is another story. The most common source are cathode-ray tubes in television sets and computer monitors. When televisions were introduced, the amount of EM radiation in the X-ray wavelengths was significant, and there was significant risk for people who watched for excessive periods. With time, televisions have been designed with better shielding, lower power consumption, and alternative projection technology, all of which have reduced the amount of EM radiation. Sources of gamma radiation in the home can be building materials, some decorative pottery, sculpture and rocks, and specialized devices (detectors, etc). There have been cases where buildings were constructed of concrete where its gravel was from uranium mine tailings. In such cases, gamma radiation exposure was high, as was radon exposure. UV radiation arises only from black lights or tanning equipment. People typically are exposed to higher doses than the indoor exposure by being out in the Sun. Lately, lasers have been used more in homes and provide yet another source of radiation. The EM radiation from

lasers is in the visible range of the spectrum and can damage the eyes if not used properly. Otherwise, all these forms of radiation are damaging only with long-term exposure, in which there are no symptoms

### MISCELLANEOUS INDOOR AIR POLLUTION

Two of the most dangerous forms of indoor air pollution do not fall into any of the other categories. Radon is considered to be the most dangerous natural environmental hazard and second only to ETS in overall danger. Asbestos is one of the few pollutants that have a certain link to cancer rather than just an indication through epidemiological studies. Both of these pollutants are a concern only in indoor air. Outside, in almost all cases except around mines, they are far too diluted with fresh air to be a real problem.

#### Asbestos

Asbestos was once considered a miracle mineral, and, as such, it was widely used. It is composed of very long hairlike fibers that are resistant to flame and heat. For this reason, asbestos was used in a variety of applications that required flexible strength and/or heat resistance. It was used in brake pads and clutch plates in automobiles; insulation for heating systems; gloves, tongs, and many other devices for working with flames and fires; in ironing boards, stoves, hair dryers, and other household heating devices; and in floor tiles and house shingles, among many other applications. Asbestos was recognized as a problem only after shipbuilders who had sprayed finely ground asbestos on ship panels during World War II began to sicken in unusual numbers. They had asbestosis, or scarring and fibrosis of the lung tissue, from heavy occupational exposure to fine asbestos fibers.

There are many kinds of asbestos. By far the most common is chrysotile, which makes up more than 90 percent of all asbestos and is linked to asbestosis. Crocidolite is a much less common form of asbestos that has also been linked to mesothelioma, a rare asbestos-related lung cancer. Usually, asbestos-related diseases are considered to result from a lifetime of heavy exposure, although there is strong debate about this point. Otherwise, there are no symptoms of asbestos exposure. It is suggested that there is a synergistic relationship between smoking and asbestos exposure, increasing the risk of lung cancer up to fivefold.

For many years, when asbestos was found to be present in buildings and homes, it was removed. It was found, however, that the removal process put

far more asbestos into indoor air than would have happened had it just been left alone. As a result, the recommendations were changed to encapsulation of the asbestos-bearing feature such as pipes where possible as long as it is intact.

#### Radon

Radon is a naturally occurring colorless and odorless gas that exists in most indoor air. It is produced during the radioactive decay of uranium 238 through a decay series to lead 206, a natural process that takes place continuously in most rock and soil. One step in this decay series is radium 224, which decays to radon 222. If the radium atom is on the surface of a mineral grain, the decay will eject the new radon atom into the open pore space and into soil gas or groundwater. Radon is the only gas in the decay series. The radon can be drawn into the basement of a house through cracks, French drains, sumps, or dirt floors by any process that reduces the pressure in the basement. The most common of these occurs in winter when a house's heating system heats the indoor air, making it less dense and causing it to rise, thus drawing soil gas into the basement. Houses with well water may also have additional radon introduced into the house through the water supply. The radon that was released to the groundwater is liberated to indoor air if the water is agitated, such as in a shower, washing machine, or dishwasher among others.

Radon is a noble gas, and, as such, it will not react with anything; nor can it be filtered using conventional methods. That is why it does not simply react with the soil and remain in the ground. The radon itself is harmless but decays to form polonium at a rate of 3.82 days per half-life. Polonium is a highly charged solid that sticks to lung tissue or to dust in the air, which is then breathed into the lungs. The polonium decays in a matter of seconds, emitting 7.6-MeV alpha decay. Normally, alpha decays are harmless because they can only travel 0.5–1 inch (1–2 cm) before expending their energy. If attached to lung tissue, however, they can cause mutations in the nearby cells. A sufficient total of mutations can develop into lung cancer, especially if the cells are already weakened from smoking.

The U.S. Environmental Protection Agency recommends an action level of 4 picocuries per liter. Below this, no action is required, but, at or above it, remedial actions are recommended. The level of 4 picocuries per liter over a lifetime of exposure is suggested to increase the risk of lung cancer. Otherwise, there are no other symptoms of radon exposure regardless of its concentration.

**influent/effluent streams** Streams are flowing bodies of water that occur on the surface of the Earth. They begin at the headwaters, typically in elevated terrains where several smaller streams coalesce to form larger streams. The smaller streams are tributaries, and there is a ranking system of orders, in which a first-order stream is the main trunk, and smaller streams have higher numbers of orders. Streams are fed by drainage basins, which are areas of lower elevation topographically bounded by drainage divides. The watershed of such an area includes the groundwater component, as well as the surface water. The water in a stream may be from runoff during precipitation events, runoff from thawing of ice and snow, or input from groundwater sources.

Groundwater is primarily recharged from infiltration of rainwater or meltwater into the soil. It passes through the *vadose zone*, which is rock and soil that are normally dry but through which water percolates, and into the *phreatic zone*, which is rock and soil that are constantly saturated with water. The top of the phreatic zone is the *water table*, whose height (depth) varies with the season and precipi-

tation events. As does surface water, groundwater flows down slopes but in the subsurface and at much slower rates. The rate is dependent upon the type of soil, sediment, or rock through which the groundwater flows. More precisely, it is the properties of the material, the hydraulic conductivity and transmissivity, in conjunction with the slope that determine the rate of groundwater flow. The topography of most areas, the hills and valleys, can be used to determine flow direction and relative rate of the groundwater and surface water. Streams interact with the groundwater system in a very intimate relation.

#### **INFLUENT OR EFFLUENT STREAMS**

If water infiltrates the bed of a stream and enters the water table, thus reducing the surface water and increasing the groundwater volume, the stream is termed *influent*, because it flows into the water table. Influent streams are common in dry areas, where the water table tends to be deep. The vadose zone is large and deep in these areas. Surface water in these areas is the major mode of recharge for groundwater in the shallow aquifer. The process has the effect of reducing the size of the stream as it flows toward the mouth, which is the opposite of what would normally be expected.

By contrast, if groundwater emerges from a spring in the bed or side of the stream, thus increasing the surface water at the expense of the groundwater, the stream is termed *effluent*. This volume of water in the stream that originated from groundwater is called *base flow*, and it constitutes the major water component of the stream. Base flow allows streams to keep flowing even when there has been no rain for a long time. The springs, or seeps, in or around the stream are areas where the water table intersects the ground surface. This situation requires a very shallow water table, which, in turn, requires significant and regular precipitation in the watershed to keep the volume of groundwater high. Vadose zones in these areas are thin and small.

Whether a stream is *influent* or *effluent* is a matter of location and time. A stream may be *influent* during a dry season and *effluent* during a rainy season. In some streams, even daily precipitation can switch a stream from *effluent* to *influent*, and vice versa. Influence versus effluence may also vary from location to location along a stream. A stream may be *effluent* at its headwaters but *influent* farther down along its course, for example. This dichotomy is typical of streams that flow out of mountains and across dry areas such as in the southwestern United States. There are any combination of conditions of influence and effluence along the length of a stream. The sys-

**A lagoon such as this located in the former German Democratic Republic can be used to store large quantities of wastewater prior to treatment. It can also act as a source of groundwater and surface water contamination if not properly managed. (imagebroker/Alamy)**

tem of interaction of surface water and groundwater is very dynamic.

### STREAMS AND POLLUTION

This interaction of surface water and groundwater explains how polluted groundwater may pollute a stream, or vice versa. A pollutant spill from a tank or chemical plant produces a plume that spreads away from the source in the direction of groundwater flow. If a stream is effluent, the pollutant will enter the stream with the groundwater. Leaky and overflowing septic systems cause special problems in this interaction. The closer the source of pollutant is to the stream, the more the stream will be polluted because the aquifer will tend to filter the pollutant. This addition of pollutant to a stream from groundwater may significantly degrade the quality of surface water along its length and causes special problems in industrial areas. Even if there is a community effort to clean and reduce pollution in the river, it can remain significantly impacted.

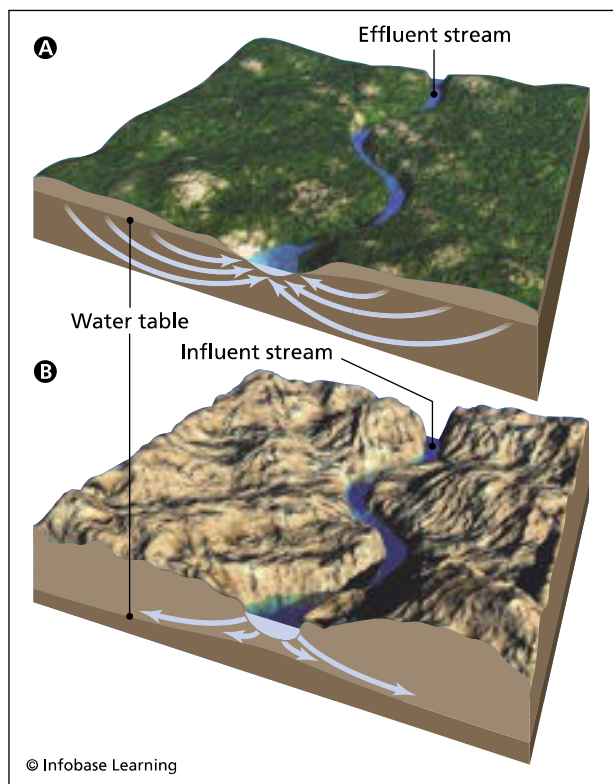

Polluted influent streams may also introduce pollutants into the groundwater system but not as frequently. The typical long travel distance through the

vadose zone to the water table will significantly filter the infiltrating water. On the other hand, many pollutants float on water, especially if they are hydrocarbon derivatives (light nonaqueous-phase liquids [LNAPLs]). Water from influent streams infiltrates the bed of the stream, thus removing cleaner water and leaving the more polluted water in the stream. In this case, the stream becomes more polluted along its length even if there is no apparent source for the pollution. This can only occur if the stream is slow and calm because turbulent flow keeps the pollutant well mixed into the stream water. In cases of dense pollutants (DNAPLs), however, groundwater may be easily polluted by stream water because the pollutant preferentially infiltrates the bed. This situation is even more dependent on stream velocity because very slow flows are required to maintain stratification of the water.

**inorganic pollutants** There are two basic divisions of industrial pollutants, organic and inorganic. Organic pollutants are linked to some kind of past or present biologic activity, or they are synthesized in a laboratory. They must include a bonding configuration that includes carbon and hydrogen but almost always includes oxygen, as well. These molecules may include other elements such as chlorine and bromine, but they are limited. These medium- to long-chain organic molecules can be broken into safer short-chain organic molecules and/or water and carbon dioxide, none of which bears any resemblance to the original pollutant. Organic pollutants actually serve as food for microorganisms in many

cases, supplying carbon for energy. The main elements in organic pollutants—carbon, hydrogen, and oxygen—are the basic building blocks of all life and are, therefore, in everything living.

In sharp contrast, inorganic pollutants are composed of elements that cannot be converted into anything else. They are naturally occurring and were part of the original components of the Earth. It is only the concentrating of them or combining of them with other elements into compounds that makes them dangerous. If organic pollutants are released into the soil, water, or even air, they will eventually be converted into other simple and common compounds. Inorganic pollutants will remain as they are until they are removed; that means that they could be there literally forever. Many inorganic pollutants are enigmatic in that trace amounts of them are nutrients that are necessary to life but excessive amounts can be highly toxic. As nutrients, they are commonly called minerals and can be seen on the labels of most multivitamins. In fact, they occur in virtually all foods. It is not only the quantity that separates nutrients from toxins but also their valence state. Oxidation, or reduction, of the inorganic element in chemical complexes can determine their toxicity. In general, water-soluble compounds are less toxic. For example, hexavalent (+6) chromium is very toxic, whereas trivalent (+3) chromium is far less toxic and even included in vitamins.

Although numerous subdivisions can be made for inorganic pollutants, for this discussion, they will be limited to heavy metals, nonmetals, radioactive elements, and miscellaneous inorganic pollutants.

### HEAVY METALS

Heavy metal pollutants include all of the metallic elements that are considered to be potentially dangerous. Originally, the term applied to metals with density greater than 6.0 g/mL, but this reference is less accepted than it once was. The most dangerous of the heavy metals are arsenic, cadmium, chromium, lead, mercury, nickel, and selenium, but other metals such as antimony, copper, molybdenum, tin, titanium, and zinc may also be dangerous at higher concentrations. Even metals that normally do not fall in the toxic category such as aluminum, iron, and magnesium can be dangerous at high enough dosage. Exposure to most heavy metals occurs only at mines and contaminated industrial sites and especially inactive sites. Soils in these areas require active remediation and can cause a significant threat to public health if not corrected properly.

The most dangerous and widespread of the heavy metals is lead. Its use was so widespread during the

industrial age up until the late 1970s that virtually everyone was exposed to it in unhealthy doses. It was in gasoline and consequently automobile exhaust, in all oil-based paint, and in plumbing everywhere in the United States. Although bans have reduced its current usage to that of many of the other heavy metals, it is still present in almost all homes built before 1970 and in all soils around those houses, as well as along the sides of roads built before that time. Peeling paint in old houses is still a significant threat to public health. Considering that lead accumulates in the body and decreases mental capacity, the cost to society of having used lead so freely may be unimaginable.

The next major threat is from mercury. In addition to being used in wool felt production, it was widely used in latex paint for many years before that use was also banned. It is still released into the air from older coal-fired power plants. The public exposure to mercury may have also been significant, and it too accumulates. Mercury released and left in the environment can pose another threat if it becomes methylated by biologic action or by industrial processes. Methylated mercury is very dangerous. One drop of dimethyl mercury, for example, can kill a person. Chromium poses similar problems with extensive use as a coating for less resistant metals and conversion to a dangerous form, hexavalent chromium, by biologic activity.

### NONMETAL POLLUTANTS

There are many more nonmetal inorganic pollutants than metals. Most are not as poisonous as the heavy metals, but many are far more widespread. Sulfur and nitrogen, for example, are major components of air pollution as oxides. Sulfur dioxide and nitrogen dioxide convert to sulfuric acid and nitric acid, respectively, when combined with water and make acid precipitation. Fallout of airborne nitrogen to the surface and open water also acts as a fertilizer that drives eutrophication in freshwater and dead zones in ocean waters. Phosphorus, another nonmetal pollutant, can also act as a fertilizer and contribute to eutrophication. It was removed from laundry detergents several years ago for this reason. Other nonmetals such as barium, bromine, chlorine, and even forms such as ozone are dangerous. They too must be remediated but, because they have non-point sources, it can be difficult to do so.

### RADIOACTIVE POLLUTANTS

There are several types of radioactive pollutants, both natural and human made. There are natu-

rally occurring radioactive elements in all soil and rocks. In low concentrations, they are not considered to cause problems. If they become concentrated by natural or anthropogenic processes, however, they can be quite dangerous. The most well-known of the radioactive pollutants is radon. This radioactive gas is inert and cannot be filtered. It can infiltrate any building or home through openings in the subsurface walls and floors or through the water supply. Radon continues to decay while in indoor air and even inhaled air until it changes into polonium, which is a reactive solid that decays very quickly. If the polonium adheres to lung tissue, it can cause mutations that could lead to lung cancer. The U.S. Environmental Protection Agency estimates that about 25,000 people die each year from exposure to radon, making it the worst environmental hazard. Radium is also naturally occurring and can occur in high concentrations anywhere there are concentrations of its parent uranium. Radium too has been linked to cancer.

When the first atomic bomb was tested in the Nevada desert in 1945, it ushered in a new age of human-generated environmental radioactivity. The first devices used fission processes, which required concentrated uranium or plutonium and released them to the atmosphere upon detonation. Later, fusion-type devices, or hydrogen bombs, did not produce significant radioactive fallout from the fusion reaction, but a fission device was required as a starter for it. The fusion explosion obliterated the fission products and by-products and delivered them as radioactive fallout. The regular testing of nuclear devices during the 1950s and 1960s during the cold war generated fallout all over the world. This testing eventually led to treaties to protect public health. Before this could happen, however, some 2,000 nuclear tests were staged. In addition to the uranium and polonium, common fallout included tritium and cobalt.

Emissions from nuclear blasts and nuclear power plant disasters, as well as the waste generated by these two sources, are considered high-level nuclear waste, which must be handled very carefully and stored. There is also low-level radioactive waste from medical procedures and certain industrial processes. It must be disposed of carefully, as well, but the constraints are not as stringent.

### MISCELLANEOUS INORGANIC POLLUTANTS

There are several inorganic pollutants that are not dangerous because of their chemistry but rather their physical form. The most infamous of these is asbestos. Asbestiform minerals, or asbestos, is a minute

grain of certain types of minerals that have a very long and thin aspect ratio. The mineral fragments are inhaled and penetrate the lung tissue, where they act as an irritant. This irritation can cause scarring of the lung, which is called asbestosis, or even a form of lung cancer that is specific to asbestos exposure, called mesothelioma. This disease results only from exposure to amphibole asbestos such as crocidolite, which is a very minor component of most asbestos. The most common type of asbestos is chrysotile, which has never been shown to cause cancer.

Silica dust like that used for sand blasting can also be inhaled and scar the lung tissue. This disease is called silicosis and can severely reduce lung function. Inhaled fibers from fiberglass insulation can also cause silicosis. Even inhaling sawdust is dangerous primarily because of the lung irritation it can cause. It, however, is an organic pollutant.

**in situ groundwater remediation** Technologies related to the remediation of groundwater can be divided into two categories, those that require the groundwater be extracted and taken to the surface for treatment (ex situ) and those that operate in place within the subsurface (in situ). Each has advantages and disadvantages, and the selection of one technology over another is largely dependent on such factors as contaminant type, site conditions, and the

objectives and costs of the remedial program. This description examines in situ technologies for the cleanup of contaminated groundwater.

For ex situ technologies to be effective, contaminated groundwater must be recovered or removed (pumped out) from the water-bearing zone in a way that provides a steady and reliable flow to the treatment system. Ex situ methods take the groundwater and dissolved contaminants to the treatment system. In situ groundwater remedial technologies describe or define a treatment process whereby removal of the contaminated groundwater from the aquifer, or water-bearing zone, is not necessary. Instead, the introduction and dispersal of treatment materials into the aquifer, or water-bearing zone, clean up the contaminant. Essentially, in situ technologies are designed to take the treatment method to the contaminant.

In situ methods often are preferred by regulatory agencies because they usually do not generate wastes that require further treatment or land-based disposal. Wastes are primarily sludge from wastewater treatment plants. They also tend to be less disruptive to existing land uses, are less expensive and safer to implement, and are more readily accepted by the public. They are the best choice if the contaminant mass is present over a large area or if the source of the contamination cannot be addressed by using conventional excavation techniques, for example, if it is under a building. In situ technologies, however, require more preconstruction design information, and using them can be difficult if subsurface conditions are not well characterized or behave differently than anticipated.

There are two basic types of in situ groundwater remediation technologies, those using physiochemical processes and those using biological processes. Each has its own set of advantages and disadvantages, but all are only as effective as the information upon which they have been designed.

#### HYDROFRACTURING AND PNEUMATIC FRACTURING

With ex situ technologies, there are a number of ways to capture the groundwater and get it to the treatment system. The objective of in situ methods is to rely on the naturally occurring patterns of groundwater flow to ensure an even and uniform dispersal of the treatment medium being added to the aquifer or water-bearing zone. The problem is that subsurface conditions often vary widely, especially over large areas, and groundwater flow patterns may have to be enhanced to ensure that the treatment medium has adequate access to all areas of the aquifer where contamination is present.

Hydrofracturing is a technique that, when properly applied, can greatly expand the ability of a treatment medium to interact with the contaminant. Developed primarily to enhance recovery from low- or slow-producing oil wells, hydrofracturing, or “hydrofracing,” is used in environmental applications if subsurface soil or bedrock conditions do not produce acceptable groundwater flow. Hydrofracturing expands or enlarges existing flow pathways or creates new ones via blast-enhanced fracturing, or pneumatic fracturing.

At sites where contaminated groundwater is present in bedrock fractures and cracks, blast-enhanced fracturing is the preferred method of hydrofracturing. Boreholes are drilled into the rock and then packed with explosives. Once explosives are detonated, the resulting expansion opens up existing fractures in the bedrock and creates new fractures and open spaces for the groundwater and treatment medium to flow through and mix with the contaminants.

In pneumatic fracturing, boreholes are drilled through the contaminated zone and short (about two-foot- [0.6-m-] long) sections are quickly pressurized by 20-second bursts of compressed air. This

breaks up an area around the borehole. Inflatable packers, rubber balloonlike devices, are used to separate the zones within the borehole being fractured. The packers are lowered into the borehole and inflated to form a secure seal to contain the energy from the charge of pressurized air or water. The charge is directed outward or laterally into the formation being fractured. The process is repeated throughout the contaminated zone. A slurry of sand and a thickening agent, such as guar gum, are sometimes added to the compressed air that is injected into the borehole. An enzyme then is pumped into the borehole that dissolves the guar gum into a thin fluid, which is removed, leaving the sand grains to hold open the new fractures.

Care must be exercised when deciding whether or not to use hydrofracturing. In the subsurface it is largely an uncontrolled process, and the additional breaks it creates in the water-bearing formation can provide new contaminant migration pathways. The uneven distribution of fractures can still leave zones of low hydraulic conductivity even after hydrofracturing is completed. A thorough understanding of underground utility lines is also necessary in order to prevent unplanned service disruptions.

**Block diagram showing contaminated groundwater flowing through a permeable reactive barrier (PRB) containing metallic iron that reacts with and neutralizes the organic solvents, thereby remediating the water**

**Schematic flowchart illustration of how phytoremediation processes remove contaminants**

### DIRECTIONAL WELLS

Another way to enhance or improve the ability of a treatment medium to interact with the contaminant mass is through the use of directional wells. Since the late 1980s, directional drilling has been used at sites to assist in the remediation of contaminated soil and groundwater. Typical wells are vertical; they begin at the surface and extend straight down until they intersect the water table. They are drilled using a bit mounted on the end of a rigid metal pipe that is driven by a gear assembly mounted on the body of a truck or trailer. Directional drilling, originally developed for the oil industry, allows the drill bit to be routed or maneuvered to an angle from 90° to almost 180°. This allows a well to be installed in which the treatment medium can be introduced or injected directly into the contaminant mass, even if it is under a building or roadway or spread out over a large area. This type of well also is more consistent with aquifer flow patterns, as groundwater tends to move faster laterally than vertically.

There are two ways to install directional wells: trenching and drilling. To install a trenched horizontal well, a ditch or furrow is excavated from the surface to the top of the contaminant zone or water table using a backhoe, excavator, or trencher. The well screen is placed in the trench, surrounded by a layer of coarse gravel. Sometimes, the well screen is wrapped with a filter fabric to prevent clogging

of the screen by silt and clay. The remainder of the trench is backfilled to a usable grade or level with the soil removed from the trench, or clean fill is taken onto the site. Installation of parallel trenched wells at varying depths is effective at forming a high hydraulic conductivity treatment zone, where remedial additives and treatment medium can be introduced quickly to the contaminated groundwater as it migrates past the trenches.

To install a directional well, a special drilling rig is needed. For this type of installation, the borehole is started at a steep angle (45° or more) that gradually flattens to horizontal with depth. Sensors near the tip of the bit send information back to a control panel on the drilling rig that allows the operators to change the angle, speed, depth, and direction of drilling. Progress is carefully monitored, and the direction, depth, and angle of the borehole are steered or adjusted around subsurface obstructions such as buried utility lines to ensure complete contact with the contaminant mass. Although wells installed with directional drilling generally have narrow diameters, they can be constructed much deeper (40–50 feet [12.2–15.3 m] below the surface) than trenched wells. If a directionally drilled borehole enters and then exits the subsurface, it is called a continuous, or double-end, completion. Wells are easier to complete in these types of boreholes because reaming tools and well screens can be pulled backward from the

opposite ends. Single-end completion, or blind, holes are those where the drill bit enters and exits the subsurface from the same place.

Directional wells are more expensive to install than vertical wells, but because they are able to access the contaminant mass more efficiently, fewer wells usually are required to deliver the treatment. Directional wells have limitations. The depth to which they can be installed is fairly shallow, either by trenching or directional drilling, usually limited to about 100 feet (30.5 m) in depth. They are also not suitable for use in areas where the depth to the top of the water table has large variations, either seasonally or with tidal influences.

### PHYSIOCHEMICAL METHODS: DUAL-PHASE EXTRACTION

Some in situ technologies use chemical and physical processes operating on a molecular level to extract, transform, or reorganize the contaminants into less harmful substances or substances that are easier to collect and manage. These technologies can be broadly characterized as physiochemical methods.

Although it does not meet the strict definition of an in situ technology, dual-phase extraction (DPE) is

typically classified as such because it does not involve soil excavation. DPE removes from the subsurface both liquid separate, or floating “free,” contaminant product and/or impacted groundwater and gaseous contamination. There are two basic types of DPE systems, single-pump and multipump. Single-pump systems use a large suction pump to draw both liquids and vapors from the aquifer into an extraction tube or well. From there, the combined vapor-liquid waste is sent to a treatment system. Multipump systems use separate pumps to remove groundwater and/or free product and vapors for collection and treatment at the surface. DPE systems evolved as soil vapor extraction began to be combined with groundwater pump and treat systems to maximize withdrawal rates and speed the remedial process.

As the groundwater table is lowered, additional contaminated soil areas are exposed so contaminants are removed from both above and below the water table. An added benefit of DPE is that it introduces air to the subsurface and encourages bacterial degradation of contaminants, similarly to bioventing. DPE also is called multiphase extraction or vacuum-enhanced extraction and has a well-demonstrated record of proven performance at numerous hazardous waste sites.

Block diagram illustrating a shallow French drain or interceptor trench

### IN-WELL AIR STRIPPING

For in-well air stripping or in-well vapor extraction, in situ vapor stripping, recirculating wells to work efficiently, bubbles, and circles are needed. Although several commercial variations of this technology have been developed, they all introduce air into a circular flowing pattern of groundwater entering a well. The process takes place in three steps:

**Step 1.** A specially designed well (sometimes called a circulating well) is installed in the contaminated groundwater. This well has an upper and a lower casing separated by a barrier, such as a metal plate, rubber seal (packer), or cement/bentonite grout. This barrier restricts water flow direction in the well to in through the lower screen and out through the upper screen. The lower screen is installed below the water table, whereas the upper screen is installed across or above the top of the water table.

**Step 2.** Air or an inert gas such as nitrogen is introduced near the bottom of the lower screen and bubbled up through the groundwater. The presence of these bubbles decreases the density of the groundwater, and it rises, moving from the lower portion of the well, past the hydraulic barrier, and into the upper portion of the well. These bubbles also serve to strip off VOCs present in the groundwater. Resulting off-gases are collected by

a suction tube and transferred to an aboveground treatment system.

**Step 3.** Once the groundwater enters the upper casing of the well, it is allowed to infiltrate or reenter the contaminant zone to help flush out residual concentrations of VOCs that may be present in the soil or aquifer. This pattern of rising and infiltrating groundwater forms a circulation cell or zone around the well, which continues until VOCs detected in the groundwater meet regulations. The introduction of air also can help oxygenate the groundwater and enhance bacterial degradation of contaminants.

The area around the recirculating well through which groundwater flows in a circular pattern is called the circulating well's area of influence. Depending on subsurface conditions, these areas of influence can extend tens to hundreds of feet from the circulating well. Often, more than one circulating well is installed so that their areas of influence overlap and form a hydraulic barrier to control off-site migration of contaminated groundwater. The in-well stripping method can be modified by introducing chemical additives such as nitrate into the circulating well to support or enhance bioremediation.

In-well air stripping works best on organic compounds that are volatile and do not adhere well to soil. These types of contaminants include halo-

**Illustration showing a storage tank of potassium permanganate attached to an injection well system built to remediate a trichloroethylene (TCE) release**

**Illustration of a subsurface map view of electron acceptor utilization zones in a dissolved contaminant plume with the operative chemicals in each zone**

generated and nonhalogenated volatile organic compounds (VOCs) and nonhalogenated semivolatile organic compounds (SVOCs). Site conditions, however, can greatly influence the effectiveness of this technology. Vertical changes in soil and sediment types with depth interfere with the ability of the groundwater to flow evenly into the circulating well. The introduction of air may result in the oxidation (precipitation) of iron, magnesium, or other metals that may build up and foul the system. Aquifers that have water tables close to the surface may not have enough of an unsaturated zone to allow a circulating pattern to be established.

Despite these drawbacks, circulating wells are an attractive remedial technique. Operational costs related to pumping are usually lower because groundwater does not have to be taken to the surface for treatment. State and federal permitting requirements are usually minimal because the captured groundwater is not discharged to a surface water body or sewer.

### STEAM EXTRACTION

Although expensive, one of the most effective ways to remove contaminants from the subsurface is with steam or hot water extraction. Its technological basis is quite simple: Steam is injected into the contaminant mass and vaporizes volatile and semivolatile contaminants. A vacuum extraction system

then is used to recover the vaporized components to an aboveground treatment system for distillation and recovery, incineration, or circulation through a filter.

In the most basic design, the injection wells are placed in the center of the contaminant mass, with the extraction wells positioned along the edges. Steam is injected either above or below the water table depending upon the location of the contamination at a pressure greater than the hydraulic pressure present in the aquifer. At the same time, the extraction wells are activated, to encourage the flow of volatilized contaminants toward them. As the steam front advances through the subsurface, it pushes the contamination in front of it, toward the extraction wells. Soil temperature probes are installed between the injection and extraction wells and, when the area between the two reaches the steam temperature, the flow of steam is reduced to the amount needed only to maintain the temperature in the soil. Another way to detect that the correct soil temperature has been reached is that steam starts to appear in the extraction wells. Many VOCs and SVOCs have boiling points much lower than that of water, and remediation (volatilization) is often rapid.

In some commercial systems, hot water is used in place of steam. The hot water flushes the contaminants into the extraction wells, where they are separated

**Diagram showing leachate flowing from a waste material source and through a porous treatment medium that removes the contaminant as the water filters through, thereby cleaning the groundwater**

and collected for off-site disposal. The water is then treated and either discharged or reinjected.

As with hydrofracturing, this technology has been adapted from the oil fields, where steam injection has been used for years to reduce oil viscosity and improve the yield of older wells. In environmental applications, steam extraction most commonly is used as an enhancement or supplemental technology in combination with the primary remedial system. Steam makes contaminants more mobile and recoverable for pump-and-treat and soil-vapor extraction systems. The addition of steam also encourages bioremediation and can greatly improve the performance of bioventing and bioslurping systems. For steam extraction to be considered a viable remedial alternative, the soil must be permeable enough to allow for its flow through the subsurface, and the contaminants should be relatively volatile.

### AIR SPARGING

Air sparging injects air directly into the contaminated groundwater. As the air moves through the

aquifer, it volatilizes contaminants, acting essentially as a belowground air stripping system. Contaminants bubble out of the aquifer and into the vadose zone, where they are collected by a soil-vapor extraction system. This combination of technologies—air sparging creating positive pressure in the subsurface and soil-vapor extraction creating a corresponding negative pressure—is one of the most common remedial techniques used to treat groundwater and soil contaminated with VOCs.

As with other in situ approaches, the increased flow of air also encourages bacteria to degrade the contamination. Sometimes gaseous bacterial nutrients (propane) or chemical oxidants (ozone) are used in sparging systems to help destroy or break up the contaminants in place, reducing the need for off-gas treatment. Air sparging systems are required to operate at flow rates so that sufficient air enters the aquifer to react with the contaminants but does not cause uncontrolled discharges to the atmosphere or into the basement of a building.

The effectiveness of air sparging is dependent on the ability of the system to push air through the

subsurface. If soil conditions are variable, airflow may not be uniform enough to reach all of the contaminated zones. The deeper the contamination, and the less permeable the soil, the more difficult it will be for air sparging to be effective. Air sparging only works on those VOCs that are easily volatilized.

### PERMEABLE REACTIVE TREATMENT WALL

One way to control the flow or movement of groundwater is through the installation of a slurry or cut-off wall where a thick, impermeable wall of clay is installed below the surface to prevent migration of contaminated groundwater off a site. If a permeable substance that allows the contaminated groundwater to flow through it but neutralizes or absorbs the contaminant as it passes is used instead, it can be an effective remedial tool. This tool is a permeable reactive treatment wall or barrier. A wall or curtain of a granulated metal or other special compound is installed in the path of the migrating contamination. As the groundwater passes through this material, the

contaminant reacts with the material in the wall and is either absorbed or changed to a nontoxic form.

With no operational or maintenance costs or the need for expensive aboveground treatment systems, permeable reactive treatment walls can be a very cost-effective solution for groundwater contamination. As an added attraction, because of the passive nature of its operation, the affected property can remain in productive use after installation of the wall with little or no disruption to ongoing operations.

Walls are installed using a variety of methods and can be composed of several different types of treatment media; the most common include zero-valence or reactive metals, usually iron; chelators such as zeolite, which are selected for their attraction to a specific metal; and nonreactive sorbents such as powdered activated carbon; and bacteria-supporting medium of mulch or compost.

An especially effective wall configuration is called funnel-and-gate. These are used for wide groundwater plumes or when contamination is unevenly

**Block diagram showing the release of light nonaqueous phase liquid (LNAPL) from an underground storage tank (UST) into the groundwater system and the dual-phase extraction system installed to remediate it. The system cleans contaminants from both liquid and gas (vapor) drawn through an extraction well drilled into the plume.**

**Diagram showing plume of contaminant from a surface source extending down below the water table. A cross-sectional view of the plume shows the distribution of electron utilization zones.**

distributed throughout the water-bearing zone. The funnel portion of the system consists of impermeable wings of sheet piles or slurry walls that extend out from the treatment wall. These wings or funnels divert and direct the plume toward the permeable reactive zone in the treatment wall.

At some sites, walls are not constructed at all. Instead, treatment media are injected into closely spaced boreholes or wells. This approach, called barrier well injection, is used for narrow, relatively small contaminant plumes and can be installed quickly with little disruption to ongoing site activities. The treatment medium also can be reinjected as often as needed to clean up recalcitrant contamination.

Treatment media in the wall eventually degrade or become saturated with the contaminant being removed from the groundwater and must be periodically replaced. For example, the iron in a zero-valent iron wall being used for the treatment of chlorinated compounds such as trichloroethylene (TCE) or dichloroethene (DCE) is oxidized when it removes a chlorine atom from the TCE or DCE. The iron granules are dissolved by the process, but so slowly that the wall can remain effective for many years. Other limitations on the use of reactive treatment walls include changes in the permeability of the wall over time as metals precipitate or bac-

teria grow and clog up the pore spaces. If a plume is large, the size of the wall needed to treat it can become prohibitively expensive, both to install and to fill with the treatment medium. Subsurface utilities, local geologic conditions such as boulders, and the depth of the plume all increase the difficulty of installing a reactive treatment wall. Installation of walls greater than 80 feet (24.4 m) below the surface requires the use of expensive specialized trenching equipment.

### CHEMICAL OXIDATION

If contaminant concentrations in the groundwater are large, or if nonaqueous-phase liquids (NAPLs or “free product”) are found, the use of in situ chemical oxidation (ISCO) is often the remedial technology of choice. ISCO entails injection of chemical oxidants into the vadose zone and/or groundwater. These oxidants then attack the contaminants, reducing them to carbon dioxide and water if the reaction goes to completion. ISCO is most commonly used at those sites where the treatment of residual free product is necessary and/or where there are time constraints on remediation.

Oxidation occurs only in the aqueous phase, and this technology depends on the flow of groundwater

through the impacted area to deliver the oxidant to the contamination. It is preferred at sites with stratified soil with low permeability or where the contaminants are not very soluble or are difficult to treat such as ketones, alcohols, or methyl tert-butyl ether (MTBE). The most commonly used oxidants are hydrogen peroxide-based Fenton's reagent and potassium permanganate. Ozone also can oxidize organic contaminants but is not used as frequently. The most effective ISCO systems produce hydroxyl radicals. These radicals are very powerful oxidizing agents, followed closely in effectiveness by potassium or sodium permanganate.

### Peroxide

Oxidation of contaminants can be triggered by introducing liquid hydrogen peroxide ( $\text{H}_2\text{O}_2$ ) activated, or made more aggressive, by the presence of ferrous iron ( $\text{Fe}^{2+}$ ) into the water-bearing zone. This compound, known as Fenton's reagent, produces enormous quantities of strongly reactive hydroxyl radicals ( $\text{OH}^\cdot$ ). These hydroxyl radicals rapidly oxidize and degrade organic compounds by removing their electrons and physically breaking apart the chemical bonds that hold these big, complex molecules together. Fenton's reagent works best at sites where the pH is acidic.

### Permanganate

The oxidation chemistry of permanganate in the subsurface is complicated. Although typically injected as a liquid in combination with potassium ( $\text{KMnO}_4$ ), it has also been used as salts of Na, Ca, or Mg. Naturally attracted to organic molecules with double carbon bonds, aldehydes, and hydroxyl groups, permanganate uses such mechanisms as hydroxylation, hydrolysis, and cleavage to break apart the electrical bonds holding these large molecules together. If used in the proper amount, permanganate can reduce the removal half-life of TCE and DCE in the groundwater to between 30 seconds and 18 minutes. The half-life of PCE is about four hours. Permanganate is more stable and versatile than Fenton's reagent and is, therefore, more persistent in the subsurface than peroxide and can be used to treat larger plumes.

### Ozone

The strongest of the chemical oxidants, ozone ( $\text{O}_3$ , or triatomic oxygen), is a double threat. It can oxidize organic contaminants directly by removing electrons and destabilizing the molecule. Ozone also generates free radicals (hydroxyl radicals) that break the carbon bonds that hold the organic contaminant compounds together. Another added advantage is that

**Schematic diagram of an air sparging groundwater treatment system that pumps air into the ground and removes the vaporized contaminants by air treatment**

as the ozone itself breaks down, it generates oxygen, which can aid in the bioremediation of untreated residual contamination. Ozone must be generated at the site by an ozone generator using either compressed oxygen or ambient air and is injected as a gas into the contaminant mass. A typical application rate is about 1–10 pounds (0.45–4.5 kg) of ozone to each pound (0.45 kg) of contaminant.

These types of oxidants must be injected into the contaminant, although at sites where the groundwater is moving relatively quickly, passive delivery systems may be appropriate. In slower-moving groundwater regimes, delivery of oxidant to the contaminant zones may require both injection and extraction wells. ISCO has been used to remediate VOCs, polycyclic aromatic hydrocarbons (PAHs), petroleum products, and explosive compounds.

ISCO has limitations. Some contaminants are resistant to oxidation (beryllium, for example), and the presence of naturally occurring organic matter increases the need for additional amounts of oxidants in the subsurface, greatly increasing chemical and distribution costs. ISCO oxidants are very reactive compounds and care needs to be exercised in their handling and storage. Changes in subsurface soil conditions can cause problems during injection or infusion of oxidants, and their use is not economical for large, widely dispersed, low-concentration (<5 mg/L) plumes. Also, certain metals such as

chromium, uranium, and molybdenum may not be soluble before introduction of oxidant but could be dissolved in the groundwater by this process. Finally, ISCO relies on the oxidant's having contact with the entire contaminant mass, and, as a result, the process is dependent on the efficiency of the delivery system. Insoluble metals can form as part of the oxidation reaction ( $\text{MnO}_2$  from permanganate, for example) and can plug up the soil and reduce the ability of the oxidant to interact with the contaminant mass.

### BIOLOGICAL IN SITU GROUNDWATER REMEDIATION

In situ remediation involves creating or modifying the subsurface environment to support the use of a physical or biological process that detoxifies, removes, or stabilizes a contaminant mass. The next broad category of remedial technology relies on bacterial or microbiological processes. The success of these technologies depends on their ability to create either aerobic or anaerobic conditions in the subsurface.

#### Bioslurping

Bioslurping is a combination of two remedial technologies, dual-phase extraction and bioventing, and is used to address both contaminated soil and

Diagram showing the subsurface map view of the release of contaminated water from a contaminant source and its collection in a funnel-and-gate groundwater treatment system

**Schematic cross-sectional diagram of a bioslurping groundwater and soil treatment system**

groundwater at the same time. It captures free product LNAPL contaminant without extracting significant amounts of groundwater.

Dual-phase extraction removes separate contaminants (LNAPLs) from the top of the water table by using pumps to draw liquid and vapors from the aquifer and vadose zone into an extraction tube. This minimizes changes in water table elevation and prevents contaminants from being spread across the soil-water table interface. As the DPE system lowers the groundwater table, soil that is normally saturated with either LNAPL or water is exposed and made accessible for treatment by bioventing.

Bioventing is an in situ remedial technology that enhances the growth of contaminant-degrading bacteria by the addition of air and sometimes nutrients into the unsaturated zone. Bioventing is an add-on component to the DPE system, and air and nutrients, as needed, are introduced as the LNAPL and groundwater are withdrawn. When no more LNAPL can be recovered, the bioslurping equipment can be easily converted to a stand-alone bioventing system to complete the remediation.

Bioslurping is most frequently used to remediate soil and groundwater impacted by petroleum hydrocarbons, especially automobile and aviation fuels. It can even be cost-effectively used at sites where the water table is more than 30 feet (9.1 m)

below the ground surface. Soil permeability is an important factor in deciding to use bioslurping. The less permeable the soil, the more difficult it is to pull out LNAPL and push in air. Other limiting factors are those that are common to any bioremedial system and include dry soil, which tends to get even dryer when air is blown through it; low temperature, which slows bacteria growth; and very high or low pH, which creates hostile growth environments for microbes. Consideration also needs to be given to how water and gases recovered by the system will be treated and discharged.

### Phytoremediation

The in situ use of plants to stabilize, detoxify, or dilute contaminated soil or groundwater is called phytoremediation. Two types of phytoremediation technologies are used exclusively to address contaminated groundwater: rhizofiltration and phytovolatilization.

### Rhizofiltration

As shallow groundwater containing dissolved contaminants migrates laterally in the subsurface, it passes through the root zone (rhizosphere) of numerous types of plants. Some of these plants have the ability to adsorb onto their roots or take up into their roots these dissolved contaminants. This is

known as rhizofiltration or phytofiltration and it can operate either abiotically or biotically.

Abiotic rhizofiltration takes place outside the plant if exudates from plant roots change local pH or redox conditions and precipitate dissolved metals out of the groundwater. Biotically mediated rhizofiltration occurs inside the plant when growth and nutrient uptake mechanisms draw dissolved contaminants from the groundwater and absorb them into their root mass.

Rhizofiltration is used when the goal of the cleanup effort is to contain and remove the contaminant from the site. Compare this to phytostabilization and phytoextraction, where the plants are left in place after concentrating and fixing the contaminants in the roots or aboveground parts of the plant. In rhizofiltration, after the contaminant saturates the plant, its roots and leaves, stems, or branches are harvested, packaged, and shipped to a waste treatment facility for final disposal. It is most commonly used at sites where groundwater is contaminated with metals such as lead, cadmium, chromium, or radionuclides such as uranium, cesium, and strontium.

Plants commonly considered for use in rhizofiltration systems are certain varieties of sunflowers and Indian mustard, both of which have demonstrated their ability to remove lead, copper, and chromium from groundwater. Plants with fast-growing root systems are preferred and seedlings are the most efficient at rapidly taking up metals with only minimal light and nutrients. Plants used in rhizofiltration are germinated in greenhouses, with their roots in water rather than soil. This tends to increase their root mass and, once they are well established, contaminated water is substituted. The plants then begin a predetermined acclimation period before they are transplanted at a contaminated site. Research is currently under way to alter plants genetically to increase their rhizofiltration ability.

Rhizofiltration is best suited for treating large, shallow contaminant plumes containing low concentrations of metals in the parts per billion (ppb) range. Plants with little surface growth are used, in order to minimize disposal costs. Rhizofiltration, as do most phytoremediation technologies, works best in climates with long growing seasons, and design consideration must be given to developing a system that prevents the transfer to or bioaccumulation of contaminants in animals.

### **Phytovolatilization**

Phytovolatilization relies on contaminant removal and transfer by withdrawing the contaminant from the groundwater and exhaling it into the atmo-

sphere. This occurs as growing plants take up water and contaminant, pass it through their vascular system into their leaves, and release it to the atmosphere. To be truly successful, phytovolatilization also alters or transforms the contaminant to a less toxic or bioavailable form. This has been demonstrated at sites where selenium is transformed to dimethyl selenide gas or organic mercury is changed to less toxic elemental mercury. After being released to the environment, many contaminants also can be further degraded by other natural processes such as sunlight-induced photodegradation.

### **Enhanced Bioremediation**

Although belowground, away from sunlight and oxygen, and at low temperature, groundwater and the soil it moves through often contain a wide variety of microbial organisms that, if properly stimulated, can be extremely effective in the degradation of many contaminants. The process of stimulating the naturally occurring bacterial population present in the subsurface through the addition of nutrients and electron acceptors is called enhanced bioremediation.

Interest in and study of groundwater microbiology have increased recently as environmental scientists and remedial engineers have begun to realize how important a tool bacterially mediated degradation of contamination can be. In the early days of bioremediation science, sampling and culturing techniques provided data that indicated the number of bacteria present in groundwater decreased with increasing depth. The prevailing wisdom was that the deeper the groundwater, the fewer bacteria it would contain, and at some depth the water would be essentially sterile. By the 1970s, testing methods had become more sophisticated, and groundwater from very deep aquifers (greater than 2,000 feet, or 610 m) was found to contain significant bacterial populations.

It is easy to identify the presence of bacteria in groundwater or most other substances using a procedure called a standard plate count, in which a 0.034-fluid-ounce (1-mL) sample of the material to be tested is spread evenly over a growth medium, most commonly agar. Originally developed from potatoes, modern agar is an extract from seaweed or algae and is used as a culture medium and a gelling agent in food. The agar is mixed with sterilized water, phosphate, nitrate, and sugar or glucose, as a carbon source, and the sample is incubated at 95°F (35°C) for 48 hours. The glass container that the agar mixture is stored in is called a plate, and different combinations of agar and nutrients can be used, depending upon the types of bacteria for which

the substance is being tested. After 48 hours, the number of bacteria that appear on the plate either as pairs, chains, clusters, or single cells are counted and reported as “colony-forming units” (CFUs) per milliliter. In the United States, most drinking water is allowed to have up to 500 CFU/mL. A widely accepted industry standard for milk is 5,000 CFU/mL.

Bacteria, and indeed all life on Earth, have similar, fundamental nutritional needs. Primarily, an energy source is needed. For plants this is the Sun; for people and other higher life-forms it is oxygen. For bacteria it can be oxygen, nitrate, or other types of inorganic compounds. Nitrogen is the second most critical nutritional component. This can be provided as nitrogen gas, which constitutes some 78 percent of the Earth’s atmosphere; or ammonia ( $\text{NH}_3$ ), nitrate, nitrite, or nitrogenous organic compounds found in proteins or nucleic acids. Carbon also is an essential nutrient and is found in carbon dioxide, methane ( $\text{CH}_4$ ), carbon monoxide, or complex organic materials such as plants and the flesh of animals. Most cells also require phosphorus, sulfur, magnesium, potassium, sodium, and calcium, some in significant amounts, others only in very small amounts. Finally, all life requires liquid water in order to live, grow, and reproduce. Water provides the pathway for nutrients to enter and waste materials to leave cells, as well as being essential to energy production. Although some resting stages of cells, such as bacterial spores, can remain dormant for an extended length of time without free water, they will eventually need it to grow or metabolize. Trace nutrients or trace metals such as iron, zinc, and cobalt are also required, albeit in very small amounts. Enzymes use these metals to help catalyze or speed up cellular functions.

The mere presence of an energy source and nutrients in the environment is not enough to drive life and growth processes. They must also be bioavailable. Broadly defined as the absorption and utilization of a nutrient or energy source, *bioavailability* is the ability of a substance to interact with living systems. The way a substance becomes bioavailable is a function of its physical or chemical state, whether it tends to be adsorbed, absorbed, bonded, or precipitated as it moves through the environment. Contaminants can be bound to soil particles because of chemical, electrostatic, or hydrophobic reactions. The strength and longevity of this bonding vary as subsurface conditions change over time. Bioavailability is dependent on whether the substance can move through a physiological barrier, such as a cell membrane, and enter a living organism. For bacteria and plants, however, bioavailability is directly

related to solubility. The substance must be dissolved in water to enter and interact with these types of organisms.

Bacteria have adapted their biochemistry of energy and nutrient use in order to survive at depth in the harsh environment of an aquifer or water-bearing zone that is dark and has little to no oxygen and little carbon. Microorganisms such as bacteria obtain energy and grow using oxidation-reduction reactions that transfer electrons from a donor (oxidizer) to an acceptor (reducer). The first step in this process occurs when an electron acceptor such as oxygen becomes available to receive or take in an electron from a donor such as spilled gasoline. Through a mechanism known as the electron transfer, electrons from the donor spilled gasoline are passed along through the bacteria’s mitochondrial membranes until they attach to a final, or terminal, electron acceptor, the oxygen.

As the electrons are passed along, a variety of cellular mechanisms use some of the energy released during their transfer to create large amounts of a compound called adenosine triphosphate (ATP). Made up of one adenosine molecule and three inorganic phosphate molecules, ATP powers the biological processes of organisms. When energy is needed for growth or for carrying out of normal biological functions, enzymes cleave off a phosphate molecule from the ATP, breaking it down into adenosine diphosphate (ADP). The breakup of the ATP molecule releases chemical and electrical energy that is used by the cell to live, grow, and reproduce. As electron acceptors or oxygen become available, ADP is converted back into ATP and stored in the cell for later use. This cycle of creation of ATP, its breakdown into ADP, and its re-formation back to ATP is called cellular respiration, and it is driven by complex biochemical mechanisms that eventually produce large amounts of ATP using an inorganic electron acceptor and the electron transport chain.

Aerobic cellular respiration uses oxygen as the electron acceptor. Aerobic respiration is effective in treating groundwater contaminated by petroleum hydrocarbons present in gasoline and diesel fuel, especially benzene and naphthalene. Even if no oxygen is available, bacteria have evolved to use other types of electron acceptors to make ATP, and many of these alternate electron acceptors are more commonly available in the subsurface. They include nitrate, sulfate, iron, manganese, and carbon dioxide. The energy available from these alternate electron acceptors is more difficult to extract, with oxygen the easiest and carbon dioxide the hardest.

Anaerobic respiration, more frequently called cellular respiration, uses other electron acceptors such as nitrate, sulfate, or iron. It is not as efficient a producer of ATP as aerobic respiration, but bacteria that use cellular or anaerobic respiration are able to exist in environments that cannot support microbes that rely on aerobic respiration. Bacteria using an aerobic cellular respiration can remediate chlorinated solvents but are generally slower than aerobic respiring microbes in breaking down petroleum hydrocarbons. In situ groundwater bioremediation works on almost all types of petroleum hydrocarbons, but the short-chain, low-molecular-weight, soluble constituents such as kerosene and gasoline are degraded more rapidly and to lower residual concentrations than long-chain, high-molecular-weight, less soluble constituents such as asphalt and paraffin.

### Field Applications

Before attempting to use an in situ bioremediation technique, it is important to remove as much contaminant from the aquifer as possible. These free product contaminants can act as ongoing sources of dissolved contamination in the groundwater and represent a fire/explosive hazard if they accumulate in basements or sewers. They can also cause significant degradation of indoor air quality if they evaporate and migrate into overlying structures.

Microbial cells are composed of carbon, hydrogen, oxygen, nitrogen, and phosphorus. Within contaminated groundwater plumes, carbon and hydrogen are present in the form of gasoline or some other organic compound that has been released from an underground storage tank (UST), industrial sewer, or treatment lagoon. The whole purpose of enhanced bioremediation is to deliver electron

Cross-sectional diagram of a collection sump-and-pump system for contaminated groundwater

**Cross-sectional illustration of an impermeable (clay) groundwater barrier system with a pump-and-treat water decontamination system to remediate the contaminated groundwater**

acceptors and nutrients such as phosphorus and nitrogen to microorganisms in the subsurface. Once these limiting factors are overcome, the naturally occurring microbial population can attack the contaminant and liberate the carbon and hydrogen for additional growth and reproduction.

One way to introduce the electron acceptor into the aquifer is to extract the groundwater using recovery wells and add electron acceptor and nutrients. The treated groundwater is then reintroduced using injection wells upgradient of or within the contaminant source. Ideally, the water being extracted is treated and then reinjected, and remediation occurs in situ, without the need for an aboveground treatment system.

In situ treatment methods are usually used if the groundwater cannot be collected efficiently by recovery wells, or if the contaminant plume is too small to justify the large capital cost associated with the design and installation of a groundwater recovery system. In these situations, oxygen as an electron acceptor is added to the groundwater by either pumping air into the subsurface through an injection well or adding oxygen through the break-

down of some other inorganic compound such as hydrogen peroxide or magnesium peroxide. These compounds can be introduced through a series of boreholes, temporary well points, or existing monitoring wells.

As with oxygen, nitrate in the form of a salt solution such as sodium nitrate ( $\text{NaNO}_3^-$ ) can be circulated through the contaminant zone as an alternate electron acceptor. Although not used as commonly as oxygen, nitrate has been able to degrade gasoline and fuel oil rapidly through a process called denitrification. Benzene, however, biodegrades more slowly under this type of anaerobic condition. One of sodium nitrate's advantages over oxygen is that it is very soluble in water, delivering 1,000 parts per million (ppm), as opposed to 12 ppm for oxygen. This allows the electron acceptor to be delivered much more quickly and in higher concentrations. If excessive nitrate is added, however, it can migrate beyond the contaminant mass and create a nitrate plume.

Although nitrate is relatively nontoxic, once it is ingested, bacteria in the human body convert it to nitrite ( $\text{NO}_2^-$ ). Until infants are about six months

old, their digestive system secretes very little gastric acid, and the pH level of their digestive tract is higher when compared to an adult's. In this setting, bacteria can proliferate, accelerating the transformation of nitrate to nitrite. Once in the blood, nitrite oxidizes the iron in the hemoglobin of red blood cells to form methemoglobin, which does not have hemoglobin's oxygen-carrying ability.

Iron is a common element that can be an electron acceptor, but its oxidation state is a problem. In groundwater, iron occurs as either reduced soluble ferrous iron ( $\text{Fe}^{2+}$ ) or oxidized insoluble ferric iron ( $\text{Fe}^{3+}$ ). The atmosphere is oxygen-rich, and most of the iron found on and near the surface is oxidized and insoluble ferric iron, in the form of ferric hydroxide ( $\text{Fe}(\text{OH})_3$ ). Ferric hydroxide is a good electron acceptor, and its reduction to ferrous iron by bacteria (called iron reducers) liberates energy that can be used by these bacteria for growth, reproduction, and associated degradation of groundwater contaminants. Ferric hydroxide, however, is not very bioavailable. Once oxidized, the ferric iron quickly precipitates and is bound up in iron-bearing minerals such as hematite or goethite. The red or brown stains, scale, or slime that accumulates in sinks and toilets in homes using iron-rich well water are the result of ferrous iron's being oxidized to ferric iron and then precipitating. These precipitates can plug water pipes or affect the flavor and color of food and water. At high levels, they may also react with tannins in coffee, tea, and some alcoholic beverages, producing a black sludge. Iron can also cause reddish brown staining of laundry, porcelain, dishes, utensils, and even glassware.

It is a slow arduous process requiring just the right supporting geochemical conditions for bacteria to reduce the ferric hydroxide and claim the energy. These geochemical conditions of a fairly narrow range of pH, Eh, and temperature are not widely present in the subsurface, and most of the ferric iron is unused and not bioavailable as an electron acceptor. If sufficient bioavailable ferric iron is present, the reducing bacteria can degrade benzene, vinyl chloride, and other contaminants. This is a biological process, very different from the abiotic use of zero-valent or nanoscale iron to treat contaminated groundwater.

The use of ferric iron as an alternate electron acceptor to stimulate the growth of contaminant-degrading bacteria is possible. There are a number of practical limitations to overcome in introducing and maintaining sufficient quantities of  $\text{Fe}^{3+}$  into the subsurface. To improve its bioavailability, ferric iron must be mixed with organic ligands or chelating agents.

The same processes and limitations that inhibit the use of ferric iron as an alternate electron acceptor also are applicable to manganese. Most manganese in the subsurface occurs as reduced, soluble  $\text{Mn}^{2+}$ . When it has contact with the atmosphere, it quickly oxidizes and precipitates as  $\text{MnO}_2$  in minerals such as pyrolusite. Manganese can cause brownish black stains on clothing and bathroom fixtures. Soaps and detergents do not remove these stains, and the use of chlorine-based bleach intensifies them. In fact, manganese is more of a problem in water at lower concentrations than iron.

Similarly to ferric iron, manganese oxide can be used as an alternative electron acceptor but yields only about half the energy of ferric iron when metabolized by manganese-reducing bacteria. As with ferric iron, manganese oxide reduction can only take place within a narrow range of pH, Eh, and temperature, and its use as an electron acceptor for groundwater remediation is not widespread.

Sulfate reduction, although providing only modest energy yields for the reducing bacteria that change or convert sulfate ( $\text{SO}_4^{2-}$ ) or sulfite ( $\text{SO}_3^{2-}$ ) to sulfide ( $\text{S}^{2-}$ ), takes place as the bacteria utilize organic contaminants in groundwater. The sulfate acts as an alternative electron acceptor that supports the anaerobic respiration of sulfate-reducing bacteria. Unlike iron and manganese, the oxidized form of sulfate is soluble and bioavailable. These characteristics make sulfate a much better candidate as an alternate electron acceptor. Up to about 10 parts per million (ppm) of oxygen can be dissolved in water, but sulfate can have a solubility of almost 120,000 ppm. Sulfate also is considered generally nontoxic and has a secondary maximal contaminant level of 250 mg/L, based on aesthetic effects. An excess of sulfate results in a foul taste and "rotten egg" odor in drinking water. Sulfate is dissolved naturally in drinking water from such common minerals as barite (barium sulfate) or gypsum (calcium sulfate). One of the end products of sulfate reduction is the very poisonous gas hydrogen sulfide, but it is produced in very small quantities and rapidly diffuses to the atmosphere.

In the last stages of organic decay, all the electron acceptors have become depleted, except for carbon dioxide. Methanogenesis, the bacterial formation of methane ( $\text{CH}_4$ ) by the reduction of carbon dioxide, removes the final decay products of hydrogen and carbon. Special types of bacteria, those without a nucleus or membrane-bound organelles, are responsible for methanogenesis. Oxygen is a deadly poison to methanogens, and to survive they must remove it from their environment. Methanogens are present only where there is no oxygen in the digestive tracts

of animals, in deep aquatic sediments, or in subsurface contaminant plumes. Methanogenesis changes organic waste to methane, or natural gas, the same natural gas used to heat houses and power electrical generating stations. In some animals, anaerobic organisms such as methanogens convert cellulose into bioavailable nutrients.

There is no practical way to introduce carbon dioxide as an electron acceptor into the subsurface because it is soluble only in acidic conditions. As soon as the pH increases, the  $\text{CO}_2$  precipitates as the mineral calcite ( $\text{CaCO}_3$ ) or dolomite ( $\text{CaMg}(\text{CO}_3)_2$ ). Also, the reaction rate for methanogenesis is several orders of magnitudes slower than that for other electron acceptors, much too slow to be useful in cleaning up contaminated groundwater. The real value of methanogenesis is as an indicator compound. If methane is detected, all other electron acceptors have been used up and some rate-limiting condition has been reached. An electron acceptor, therefore, needs to be added to the system to continue the in situ cleanup process.

The utilization of electron acceptors occurs in a specific order as bacteria respire nitrate, iron, or sulfate and oxidize carbon-bearing contaminants to support growth and reproduction. These processes can be charted in the field to show which electron acceptor is being utilized at any point within the contaminant plume. A redox map shows how the contaminated groundwater is being broken down as electron acceptors are used up. At the edges of the plume, oxygen is still available and aerobic respiration is taking place. Deeper into the contaminant zone, dissolved nitrate, iron/manganese, and sulfate are consumed. Finally, within the heart of the contamination, carbon dioxide is being consumed and methanogenesis is taking place.

### MONITORED NATURAL ATTENUATION

A number of mechanisms are available in the subsurface to reduce the mass, concentration, toxicity, or mobility of petroleum- and nonpetroleum-based contaminants. These processes operate naturally, without human intervention, and with varying degrees of efficiency, as the groundwater moves through the aquifer. At certain sites, where slow-moving groundwater is not being used by people or the local ecology, it may be sufficiently protective of public health and the environment to do nothing but periodically check on the status of the contamination.

Although viewed with suspicion by communities that have been impacted by contamination, and very carefully evaluated by regulatory agencies, a monitoring-only approach called monitored natural

attenuation, or MNA, can be a valid and justifiable in situ response to some types of groundwater contamination. MNA is usually implemented as a remedy in conjunction with other, more proactive measures such as excavation of contaminant saturated soil or recovery of separate contaminant. It also is sometimes used as the final step in remedial treatment, replacing an in situ or ex situ method that has reached the limits of its effectiveness. A critical part of justifying an MNA remedy is being able to demonstrate that groundwater will clean itself up within a reasonable time frame compared to that for other, more aggressive measures. It generally is not appropriate for contaminants that have a high degree of persistence and toxicity in the environment such as certain types of pesticides or polychlorinated biphenyls (PCBs).

To make a case for MNA as a remedial alternative, three basic pieces of information are needed: the types and vertical and horizontal extents of contaminants, the direction and rate of flow of the contaminated groundwater relative to the community, and the ability of subsurface conditions to support the biological activity necessary to degrade the contamination within a reasonable time frame. The answers to these questions are gathered during a detailed site characterization that collects soil and groundwater samples to delineate or identify where the contamination is present. This characterization program evaluates groundwater flow direction, rate of movement, and the presence of biological activity and electron acceptor breakdown products of carbon dioxide, methane, and so on. Groundwater data are usually collected over a period of years to account for seasonal variations and to show that natural attenuation processes are working. One indication is to determine, through the monitoring data, whether the plume is shrinking, expanding, or staying the same. Another objective of long-term monitoring is to check for the presence of contaminant degradation products, which can be more mobile or more toxic than the original contaminants. Sometimes computer simulations or models can be used to shorten the data-gathering effort and help predict how long natural processes such as nitrification or sulfate reduction will take to reduce contaminant levels to an acceptable concentration. The conditions that affect biodegradation of petroleum hydrocarbons and chlorinated solvents are well known, and the efficiency of natural attenuation can be assessed with a relatively high degree of confidence.

**Ixtoc I oil spill Gulf of Mexico June 3, 1979**  
**Water Pollution** The Gulf of Mexico is a body of marine water, surrounded on three sides by land. To the north and east are the Gulf Coast states of Texas, Louisiana, Mississippi, Alabama, and Florida; to the west and south is coastal Mexico from the border at Matamoros, through Veracruz, Tampico, and Coatzacoalcos to the Yucatán Peninsula at the Bay of Campeche. It is the ninth largest body of water in the world and holds more than 600 trillion gallons (2,271 trillion L) of water. The gulf's roughly 600,000 square miles (1.6 million km<sup>2</sup>) of surface area, 1,000 miles (1,609 km) east to west and 600 miles (966 km) north to south, includes about 3,500 miles (5,633 km) of shoreline and provides habitat for an annual commercial fish and shellfish harvest estimated to be almost 2 billion pounds (0.9 billion kg) and valued at \$700 million.

The more than 200 estuaries that surround the gulf include coastal wetlands, submerged vegetation, upland areas, and marine/offshore areas. The 5 million acres (2.02 million ha) of U.S. coastal wetlands, about half of the national total, are along the gulf. These coastal wetlands serve as an essential habitat for numerous fish and wildlife species, including seabirds, wading birds, and 75 percent of the country's migrating waterfowl. The gulf also serves as a major commercial center. Seven of the busiest ports in the United States are in the gulf, including the port of

Houston, which is ranked first in the United States in foreign waterborne commerce, second in total tonnage, and eighth most active in the world.

The Mississippi River deposits more than 3.3 million gallons (12.5 million L) of water and sediment into the gulf every second, and this discharge accounts for more than 90 percent of the freshwater entering the gulf. Carried along with this freshwater, and intermixed with the entrained sand, silt, and clay, is organic matter including bits of vegetation, animal carcasses, and other once-living debris. Over time, this matter combined with the immense amount of the organic matter from the dying and settling organisms (mostly plankton) in the Gulf of Mexico itself, squeezed and heated by the crushing and unrelenting weight of the overlying sediment, formed large deposits of oil and natural gas. More than 700 billion barrels (29.4 trillion gallons or 112 trillion L) of petroleum and 5,300 trillion cubic feet (150 trillion m<sup>3</sup>) of natural gas is estimated to be present beneath the seafloor in the northern gulf. Extraction of these important hydrocarbon resources provides approximately 20 percent of the U.S. domestic natural gas and 30 percent of its oil. The offshore petroleum industry also employs more than 55,000 workers in the gulf. Mexican hydrocarbon extraction activities produce, on an annual basis, more than 2,500 million barrels (105 billion gallons or 400 billion L) of oil from Gulf of Mexico offshore operations.

#### BACKGROUND

Petroleum exploration and development activities in the U.S. Gulf of Mexico territorial waters are carried out by consortiums of privately owned and operated oil and gas companies. On the Mexican side of the gulf, those activities are the responsibility of PEMEX, or Petróleos Mexicanos, a company owned and operated by the Mexican government. Founded in 1938, partly in response to a strike by Mexican workers against American and European oil companies for better pay and working conditions, PEMEX and its 140,000 employees have made Mexico the fifth largest oil exporting country in the world, and the company contributes almost \$100 million in annual revenue to their economy.

The center of Mexico's gulf oil production is the Bahía de Campeche, or Bay of Campeche. Named for a small, thorny tree that grows in the area, the Bay of Campeche is tucked away into a curve, or bight, of the southern Mexican coastline and is bordered on three sides by the Mexican states of Campeche, Tabasco, and Veracruz. Beneath the quiet waters of the bay, about 50 miles (80 km) off

Oil bubbling into the Gulf of Mexico from the blown-out Ixtoc I well near Del Carmen, Mexico, January 1980 (AP Images)

its coastline is the Cantarell Complex, a collection of five giant reservoirs that make this the second most productive oil field in the world. Discovered in 1976, oil from beneath the Bay of Campeche supplied Mexico with about two-thirds of its crude oil until very recently.

PEMEX moved quickly after the discovery of the Cantarell Complex to begin exploration and development operations. They leased a semisubmersible drilling rig from Sedco, the owner of the rig and a worldwide oil exploration company. This rig was equipped with pontoons and columns, which, when flooded, allow it to sink to a predetermined depth and begin drilling operations. These types of drilling rigs usually are attached to the ocean bottom with mooring chains. Others use a series of computer-controlled dynamic positioning propellers or thrusters mounted on each corner of the platform to keep the rig centered over the borehole. Readily available, usable under a variety of conditions, and inexpensive compared to jack-up and other types of platforms, semisubmersible drilling rigs can operate in water depths ranging from 2,000 to 5,000 feet (610–1,524 m) and are able to be detached quickly and towed to the next location after a well is completed and placed into service.

Initial drilling went very well. The exploratory well, named Ixtoc I, was quickly drilled to a depth of more than two miles (3.2 km) below the ocean floor. During drilling, especially to these great depths, drilling mud, a special mixture of fine silt and clay, is pumped down and through the borehole both to help remove cuttings and rock debris ground up by the drill bit, and to make sure an uncontrolled release, or blowout, of oil or gas does not occur. In addition to the drilling mud, special valves called blowout preventers, or BOPs, are attached to the top of the wellhead. These valves can be closed to contain any oil or gas that suddenly rushes out of the borehole.

### THE BLOWOUT AND SPILL

On June 3, 1979, a sudden loss of drilling mud circulation took place within the two-mile- (3.2-km-) deep borehole of the Ixtoc I exploratory well. Ignoring the advice of several safety specialists working on the platform, workers withdrew a section of drill pipe and started to unscrew it. Oil and mud began gushing out, and, when workers tried to retighten the pipe, the threads jammed. When the crew was unable to secure a safety valve to the

top, special shears were deployed to cut through the pipe, but they were not strong enough. As the overlying mud poured out of the borehole, without the correct amount of drilling fluid to hold back the oil and gas, which was under tremendous pressure, it explosively forced its way out through the top of the wellhead and onto the working level of the semisubmersible drill rig. As the roughnecks and platform operators ran for their lives, the oil and gas spewing from the well ignited, and, within a few hours, the \$22-million burning drilling rig collapsed on itself and sank, settling to the bottom of the Gulf of Mexico and landing directly on the remnants of the now-broken and shattered wellhead, eliminating any possibility of quickly controlling the blowout. Oil was pouring into the Gulf of Mexico at the rate of about 400–1,200 barrels (16,800–50,400 gallons or 63,840–191,520 L) per minute.

One of the first efforts to stop the flow of oil involved the use of a small remote-controlled submersible. This attempt failed because of very low visibility and the presence of platform wreckage near the submerged wellhead, including more than 9,000 feet (2,743 m) of pipe that had been ejected from the borehole. Eventually, volunteer divers were able to approach the wellhead to engage the BOP, which was still mounted there and was acting to restrict partially or slow the flow of oil. They were successful, but the pressure exerted by the now-confined oil and gas continued to build and started to destroy the BOP, so the valves were reopened. Realizing now that there would be no easy solution, PEMEX authorized the drilling of two relief wells adjacent to Ixtoc I. Once they were completed, the oil and gas pumped from these two relief wells reduced the pressure within the Ixtoc I borehole sufficiently to allow a 1,650-foot (503-m) plug of quick-setting cement mixed with bits of canvas, steel, and lead pellets to be pumped into the borehole to stop the flow of oil. That was on March 23, 1980, almost 10 months after the initial blowout and subsequent to the release of more than 3.3 million barrels (139 million gallons or 528 million L) of oil into the Gulf of Mexico.

### THE CLEANUP

As the oil gushed into the waters of the gulf, skimmer ships and booms were positioned to contain and recover as much of it as possible. Prevailing northerly winds, however, began to push the oil toward the Texas coastline. With only two months to prepare for the arrival of an oil slick estimated to be 60 miles (97 km) wide and 70 miles (113 km) long and up to six inches (15.2 cm) thick,

booms were laid across the entrances to most estuaries and oil cleanup crews were placed on standby. Oil first made landfall on the Texas beaches of Port Mansfield Channel and North Padre Island in early August. By September, the entire South Texas coast had been oiled to one extent or another, with mousse and tar balls washing up on beaches and shorelines. Specially developed vacuum sweepers, along with rakes and shovels, were used to clean beaches rather than the more environmentally damaging heavier equipment. Almost 72,000 barrels (3 million gallons or 11.4 million L) of oil washed up on 160 miles (258 km) of U.S. beaches, and more than 10,000 cubic yards (7,646 m<sup>3</sup>) of oiled sand and other material were removed. Bird cleaning stations were set up by the U.S. Fish and Wildlife Service, but only a few dead birds were found, as many avian species bypassed the oil-covered shorelines probably because of contaminated food sources. A total of 1,400 birds were recovered and treated for oiled feathers or feet.

As summer ended, winds shifted, and oil containment efforts near the wellhead gradually became more effective. A bell-shaped cap was placed over the wellhead at the bottom of the seafloor, which helped slow the flow of oil and allowed it to be partially collected and burned at the surface. Aerial applications of oil dispersants were also sprayed regularly on the slick, and oil collecting ships and booms operated around the clock. By mid-September, thanks in part to a storm that helped wash much of the oil off the beaches and push the slick farther out to sea, the worst was over for the U.S. coastline.

The change of season winds and currents started to force the oil toward Mexico. Impacts to Mexican beaches were severe, but the government has been hesitant to release actual data or the results of the limited follow-up studies that were conducted. Newspaper accounts quoting individuals living near the coastlines of Tampico and Matamoros reported that “thousands” of seabirds had been covered with oil and died. The U.S. Fish and Wildlife Service helped airlift thousands of the endangered Kemp Ridley sea turtles from their nesting ground in Tamaulipas to unoiled beaches in other parts of the gulf. These very small hatchlings, which can grow to more than three feet (1 m) long weighing up to 80 pounds (36.3 kg), race to the ocean after breaking out of their shells and are particularly sensitive to oil pollution.

### THE AFTERMATH

PEMEX and the Mexican government denied responsibility for the blowout and refused requests for reimbursement of cleanup expenses or compen-

sation to fishermen and others impacted by the oil that washed up on Texas beaches. Tourism along Gulf Coast resorts declined 60 percent that year. Sedco, the Texas-based owner of the drilling rig operated by PEMEX, paid more than \$2 million in compensation to fishermen and resort owners. The total estimated cost of the blowout was more than \$350 million, including the value of the lost oil.

Since the Ixtoc I disaster, PEMEX continues to be beset by a number of incidents that have had major impacts on its neighbors and have raised questions about the safety of its operating practices. A series of explosions in 1992 at a PEMEX facility in Guadalajara, Jalisco, killed more than 200 people. In 1996, a sequence of massive explosions at the PEMEX petroleum storage facility at San Juan Ixhuatepec, just north of Mexico City, started a fire that killed 500 people. In summer 2007, Leftist rebels reportedly blew up and damaged four sections of a 36-inch-(91.4-cm-) diameter natural gas pipeline operated by PEMEX. These and other incidents, coupled with charges of corruption and dishonesty by many of its service station operators, point to a company struggling to balance its vital role in the Mexican economy with the need to protect the health, safety, and welfare of its operating environment.

# K

**karst** Karst is a type of landform or topography that forms in areas underlain by limestone and in relatively wet and temperate climates. Meteoric water becomes slightly acidic with carbonic acid through interaction with  $\text{CO}_2$  in the atmosphere and/or rotting vegetation on the surface in wetlands or other wet areas. This acidity can be increased in industrialized areas with the addition of sulfuric acid from sulfur dioxide and nitric acid from nitrogen dioxide, two common air pollutants. On the surface, the acidic waters dissolve the surface of the limestone, reducing the elevation of these areas. The acid waters flow into fractures and joints and dissolve the calcite in limestone below the surface, as well. The fractures expand with continued dissolution, becoming caves and caverns. As the underground cavities expand and interconnect, eventually all surface flow drains underground and flows through them in underground streams. All groundwater is contained within these caves in areas of karst.

Disappearing streams occur where a surface stream drops into an underground stream in a single sinkhole. Even with water in underground streams, the dissolution of limestone continues unabated, and the stream may drop to deeper levels, leaving dry cave and cavern systems in the abandoned upper levels in areas with deeper water tables. There are very few, if any, surface streams or rivers in karst terrains. At times, the roof of the cave can collapse, forming a craterlike sinkhole on the surface above. As is the cave system, the location of the sinkholes is controlled by fractures and fracture systems. Depending upon the severity of the collapse and the development above it, large structures such as buildings, cars, roads, and trains can fall into the cave. In some areas, this is a serious environmental hazard.

## WATER POLLUTION

Karst terrains have severe problems with water quality. Even with no human influence, the water in these areas is extremely hard (or rich in dissolved cal-

The headwaters of the river Loue in the Jura Mountains of eastern France is a spring flowing from a karst cave at the foot of a limestone cliff. (Bob Gibbons/Photo Researchers, Inc.)

**Sinkhole on John Muir Drive in San Francisco, California, 1998** (AP Images)

cium), a condition that, in most cases, causes no real adverse health effects but will clog pipes and destroy water-bearing appliances. The real problem arises because water flowing through caves is like water flowing through a very large open pipe. There is no mechanical or chemical filtering of the water, as in typical rock and sand aquifers. The water, therefore, contains virtually all the bacteria and pollutants that enter the system all along its course. Runoff from the surface enters the groundwater system directly. This especially creates problems in industrial areas where runoff may flush industrial chemicals into surface waters and directly into the groundwater system. Agricultural areas pose similar threats with fertilizers and pesticides flushed from the fields and into the groundwater.

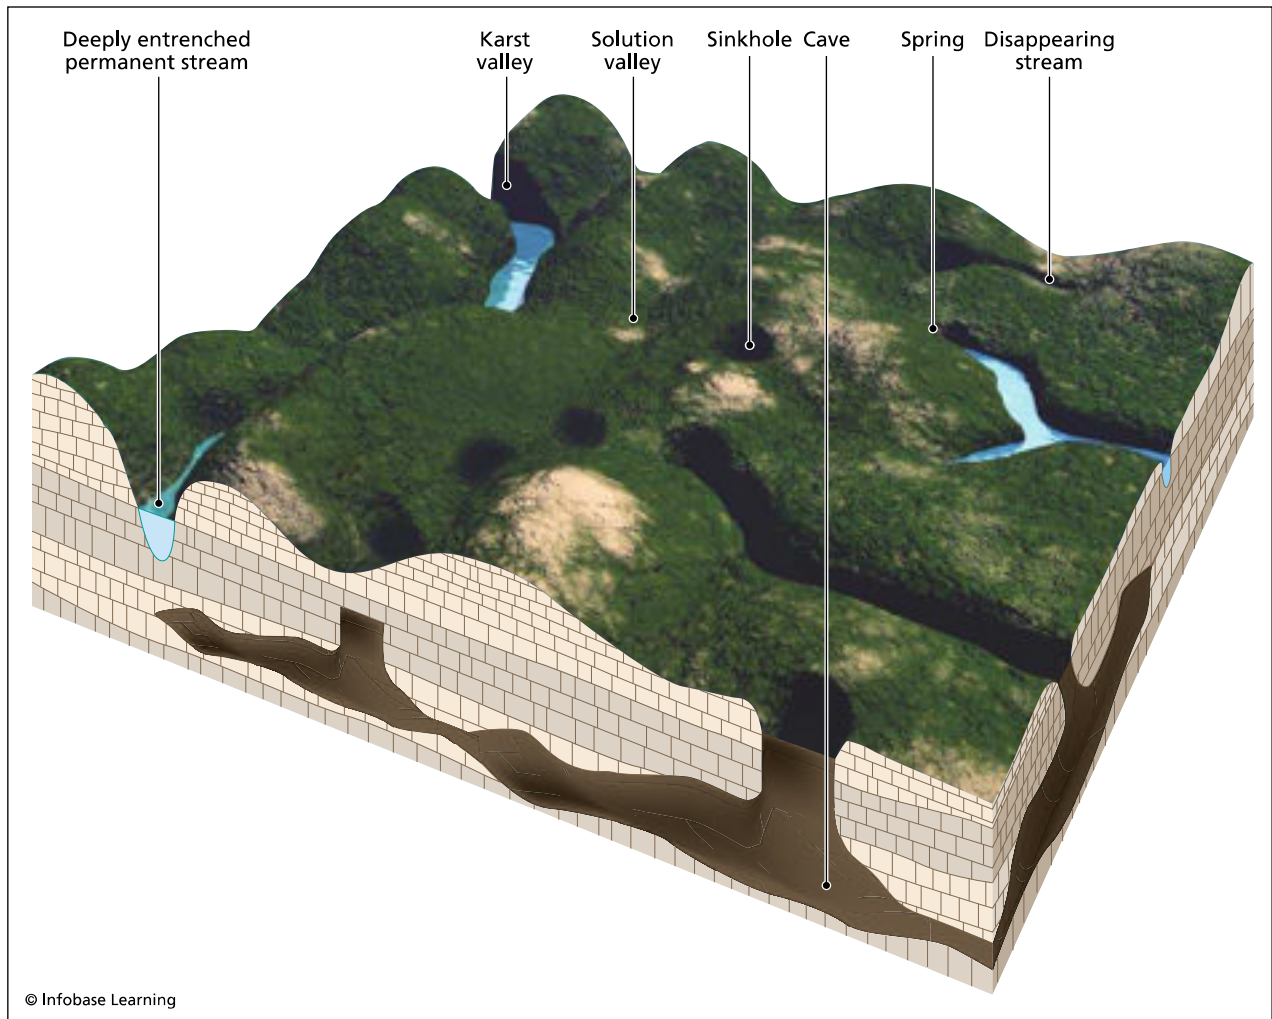

There is a story that in Egypt several chickens fell down a well in a karst area and climbed out of another well about one mile (1.6 km) away, looking no worse for wear. This illustrates the size of particles that can be carried in a karst system. A less comical example occurred in a chemical plant on the Delaware River, New Jersey, where workers arrived in the morning to find a waste lagoon had completely disappeared down a sinkhole during the night, and it was never recovered. Houses, roads,

trains, and many other structures have been known to disappear into sinkholes, either slowly or catastrophically. It is for this reason that karst areas are so environmentally sensitive as well as dangerous to develop. It is important that town planners and engineers avoid siting landfills or any other waste treatment or generating facilities on limestone terrains.

**Sinkhole in Winter Park, Florida, May 1981** (AP Images)

**Block diagram showing the typical surface and subsurface features of a karst terrain in limestone**

Zoning laws should also be carefully designed to protect the water quality.

### **SOME EXAMPLES OF KARST AREAS**

There are several examples of major karst aquifers in the United States. The largest is probably the Floridan Aquifer of Alabama, Florida, Georgia, South Carolina, and a small part of Mississippi. This huge aquifer provides water to tens of millions of people as well as to the major agricultural areas of the country. The burgeoning population in the area and heavy national demand for agricultural products have been a heavy burden for the Floridan Aquifer, which is now suffering from degraded water quality, diminished water supplies, and saltwater incursion along the coastal areas.

The Edwards Aquifer of Texas is also a limestone aquifer with karst development. It has produced some of the most dramatic artesian wells yet

found and has recorded the highest flow rates from wells in the United States. It too, however, suffers from degraded quality and diminished supplies that threaten its unique ecology.

There are numerous other karst areas in the United States that may not have such impressive aquifers but suffer from the same pollution problems. Areas with large caves and cavern systems, by definition, are areas of karst. The Mammoth Caves of Kentucky are part of a huge system that extends into West Virginia and Tennessee, but the limestone that hosts it stretches northward into Ohio and Pennsylvania and southward into Alabama. With other systems including Luray Caverns of Virginia and Howe Caverns in New York, most of the states east of the Mississippi River have karst in at least some area. Only Delaware and a few of the New England states do not have karst. There is also karst in the West, magnificently exemplified by Carlsbad Caverns in New Mexico. Karst is generally less pro-

nounced in the West because of the more expansive arid and semiarid areas.

#### Kerr-McGee Rare Earths Facility West Chicago, Illinois 1990–present Soil Pollution

The 90-acre (36.4-ha) Reed Keppler Park lies about 30 miles (48 km) west of Chicago, Illinois. Part of the almost 400-acre (162-ha) West Chicago Park District, Reed Keppler Park, or RKP, is one of 13 recreational areas serving this suburban bedroom community of some 30,000. It is used for tennis, swimming, volleyball, soccer, baseball, and softball. Surrounded by quiet residential neighborhoods, RKP's Family Aquatic Center has a 12-foot- (3.7-m-) high waterfall, a flume slide, and a six-lane, 25-yard- (22.9-m-) long lap pool.

#### BACKGROUND

The area encompassing the park was originally a quarry in the early 1900s, providing rock, sand, and gravel for the construction of nearby railroad embankments. When those deposits were depleted in the late 1920s, a large hole in the ground was all that remained. Wanting to fill this pit, the property owners opened the former quarry for use as a commercial waste dump. By 1939, five acres (2 ha) of the site was being filled with household trash, as well as some sandlike material from a local chemical plant, the West Chicago Rare Earths Facility, or REF. Operated by a series of companies between 1934 and 1973, REF extracted and concentrated radioactive elements such as thorium, radium, and uranium for use by private business, as well as by the U.S. government in its atomic energy and weapons programs. These radioactive materials were produced from monazite ore sands.

Monazite is a reddish brown cerium phosphate mineral ( $\text{CePO}_4$ ) that also is an important source or ore of such rare earth metals as lanthanum, neodymium, and praseodymium. These and other rare earth elements extracted from monazite are used in the ceramic and electrical industries, as well as for research purposes. Monazite also can contain trace amounts of uranium, thorium, and radium. It is a hard, erosion-resistant mineral that occurs as isolated crystals in igneous and metamorphic rocks and tends to weather out of these rock masses and become concentrated in placer deposits. These deposits are natural concentrations of heavy minerals that are slowly washed downhill into streams, where the lighter matrix materials are winnowed away or removed. Monazite is mined from placer stream and shorefront deposits in India and Brazil

and along the North Carolina and Florida coastlines. Other types of ore sands containing bastnaesite, a rare earth carbonate mineral, and fluor spar ( $\text{CaF}_2$ ), also were processed at the REF plant.

### **POLLUTION OF THE SITE**

For the almost 40 years that REF operated, sulfuric acid was washed through tons of monazite ore sand to dissolve the thorium and other rare earths trapped within its crystal structure. Although a highly efficient process, acid leaching had two serious drawbacks: It did not remove all of the thorium, uranium, and rare earths present in the monazite, and it left large volumes of sand for disposal.

As do all businesses, REF sought to keep its operating expenses as low as possible, and this included trying to find cost-effective ways of managing its processed sand or tailings, the leftover material from a mill after most of the valuable minerals are extracted. REF started to give its tailings away for use around the West Chicago area, and local builders and developers eagerly accepted the sand for backfill around foundations. Much of this material was spread around the REF site, but a significant amount was sent to the old quarry-turned-landfill and other areas that eventually would become Reed Keppeler Park. By 1967, when the multinational energy company Kerr-McGee pur-

chased REF, the old quarry essentially had been filled and the use of tailings generated from the site ended in the vicinity of the park. Kerr-McGee operated the facility only a few more years and permanently closed REF in 1973.

The tailings contained residual amounts of radioactive elements, primarily thorium, radium, and uranium, at concentrations posing a significant public health risk. As the unstable nuclei of these elements decay, or break down, they produce gamma radiation and give off or radiate charged protons and neutrons. If particles containing these radioactive elements are taken into the body, by either ingestion or inhalation, they can cause severe cellular and tissue damage that can lead to cancer. These radioactive elements have extraordinarily long breakdown half-lives and consequently remain at dangerous levels in the environment for many years. The potential hazards associated with radioactive residuals in the tailings were not widely recognized when the majority of the material was being distributed (1930s through 1960s).

During the early 1980s, the U.S. Nuclear Regulatory Commission (NRC) conducted an aerial radiation survey in the area of West Chicago and detected anomalously high levels of radiation in and around the former REF facility. Subsequent investigations by the EPA identified the source of the radiation and

**Excavated northern part of Kerr-McGee landfill, Illinois** (*Environmental Protection Agency*)

led to the inclusion of the REF on the National Priorities List (NPL) as a Superfund site in 1990. The EPA found that soil at Reed Keppler Park contained 286 picocuries per gram (pCi/g) of total radium with a maximal concentration in excess of 15,000 pCi/g. Most decontamination guidelines in effect at the time required the removal of soil in public areas if total radium concentrations were higher than 5 pCi/g over background levels, which in this area was about 2 pCi/g. Soil with a total radium concentration of greater than 7.2 pCi/g had to be remediated. A curie (Ci), named after Madame Marie Curie, the French scientist and Nobel Prize winner, is equal to a radioactive decay rate of  $3.7 \times 10^{10}$  disintegrations per second. (The prefix *p* stands for “pico,” a modifier meaning  $10^{-12}$ ; one picocurie, or 1 pCi, represents 2.2 radioactive disintegrations per minute.)

### CLEANUP OF THE SITE

The U.S. Environmental Protection Agency (EPA) issued an administrative order that required Kerr-McGee, the generator of the contaminated sand, and the city of West Chicago, the owners of the property, to initiate soil removal activities at the park. Beginning in 1997, radioactive impacted soil from the band shell, tennis courts, and several parking lots began to be excavated. At the old quarry/landfill where the most material was removed, the excavation was extended to below the water table and was not completed until 1999. Each of these areas was backfilled with clean fill, covered with a layer of topsoil, and restored to a usable surface grade. Final restoration activities were finished in 2000. Almost 115,000 cubic yards (87,924 m<sup>3</sup>) of contaminated material was removed and temporarily stored at the REF site. From there, it was packaged and shipped to an NRC-licensed low-level-radioactive-waste disposal facility. By 2002, EPA certified that the RKP site had been remediated and was suitable for unrestricted release.

RKP was not the only area impacted by REF operations. Three related Kerr McGee sites were placed on the National Priorities List as Superfund sites in 1990 or 1991, including the West Chicago Sewage Treatment Plant (STP) site, the Residential Areas Site, and the Kress Creek/West Branch DuPage River Site. Contamination at these locations also originated from REF, and they were remediated separately.

Between 1932 and 1973, REF donated radioactive tailings and process wastes from its operations for use as backfill and in stream bank stabilization projects at the West Chicago municipal STP. Some of this material was also mixed with landfill

wastes, and, as a result, soil was contaminated at the site. Tailings were also used as fill along an approximately 320-foot (97.5-m) section of riverbank. Over time, as a result of flooding and erosion, thorium residuals were distributed in other areas of the stream banks, floodplain, and bottom sediment.

At the STP site, radiation surveys identified an estimated 57,000 cubic yards (43,580 m<sup>3</sup>) of contaminated soil that had to be removed and disposed of properly. This was done between 1986 and 1987, but the cleanup criterion used later was found to be too high, and a second removal action focused on additional material under or beside outfalls along the bank of the river. This second removal action resulted in the excavation of an additional 6,400 cubic yards (4,885 m<sup>3</sup>) of material. River areas impacted by REF tailings were remediated through the removal of approximately 2,200 cubic yards (1,682 m<sup>3</sup>) of targeted soils and sediments (with activities above 7.2 pCi/g) by excavation. Collected wastes were packaged and shipped to an appropriately licensed low-level radioactive waste disposal facility.

Prior to excavation, targeted areas were dewatered to allow soil and sediments to dry out before they were removed. Part of the remediation included the removal, staging, and redeposition of more than 1,100 cubic yards (841 m<sup>3</sup>) of clean soil. After excavation activities were completed, a series of mitigation and restoration activities were implemented to restore aquatic and terrestrial areas that had been disturbed, including revegetation and stream bank restabilization. Later monitoring and maintenance of restored areas demonstrated that excavated areas had been restored as productive ecological habitat.

Residential properties in West Chicago also were impacted by REF. Radioactive tailings used as fill materials, sometimes mixed with topsoil, were deposited around buildings and in gardens and yards. In addition, tailings were used as filler in cement in some areas that later was used in structural foundations. In 1994, acting in response to a recommendation made by the Agency for Toxic Substances and Disease Registry (ATSDR), the EPA prioritized and began to excavate and dispose of those materials that posed the highest public health risk. These were homes with tailings adjacent to their foundations or under them in crawlspaces. Eventually more than 1,300 residential properties were evaluated for the presence of airborne gamma radiation and radon concentrations. Both surface and subsurface soils outside these homes were sampled and analyzed for the presence of thorium, radium, and other radioactive constituents. By 2002, the study area expanded to almost 2,200 properties. The EPA documented contamination in 31 percent of the homes tested.

Kerr-McGee arranged for the removal of the contaminated material from all of the impacted residences. More than 113,000 cubic yards (86,395 m<sup>3</sup>) of soil and related debris was removed and shipped to an NRC-licensed disposal facility, including contaminated soil from two schools. A former Kerr-McGee laboratory was found to contain too much mercury and thorium and subsequently was demolished after several attempts at decontamination had left the building structurally unsound. Today, the residential and other off-site properties impacted by placement of REF tailings do not present a public health hazard because the radioactive materials have been removed and there is no ongoing exposure to local residents or building inhabitants.

The Kerr-McGee Kress Creek/West Branch of DuPage River site (DuPage) is another West Chicago Superfund site contaminated with thorium and other radioactive wastes from the REF facility. The site became polluted over time as surface water runoff from REF entered a storm drain and discharged radioactive particulates washed from the site into Kress Creek. From there, stream flow moved this contamination downstream to the West Branch DuPage River. Approximately 1.5 miles (2.4 km) of Kress Creek, from the REF storm sewer drain to the creek's confluence with the West Branch DuPage River, and approximately 5.2 miles (8.4 km) of DuPage River, downstream to the McDowell Dam were impacted.

To remediate these watercourses, Kerr-McGee spent \$70 million to excavate impacted sediments of nine segments of the stream, starting with the most contaminated upstream areas closest to REF and moving to least contaminated downstream sections. Cleanup work began in 2005 and was completed in 2008.

On June 23, 2006, the Anadarko Petroleum Corporation acquired Kerr-McGee in an all-cash transaction totaling \$3.4 billion. Kerr-McGee immediately ceased to exist as an independent entity. Its Superfund cleanup obligations at West Chicago and in other areas of the country will continue to be paid for by a special fund established by the company prior to its acquisition and dissolution.

#### Kingston coal ash release Roane County, Tennessee December 22, 2008 Water and Soil Pollution

Since the late 1700s, navigation on the 650-mile (1,050-km)-long Tennessee River had been problematic. The river is divided into an upper region north of Muscle Shoals, Alabama, and an eastern, lower region in Tennessee, separated by a 35-mile (56-km) series of rapids along which the river drops 130 feet (39.6 m) in elevation. As the largest tributary of the Ohio River and one of the major watersheds in the United States, its often erratic and unpredictable character seriously hampered commerce within the seven states through which the Tennessee River flows. In an effort to stabilize the river, the War Department (later Department of Defense), in cooperation with the U.S. Army Corps of Engineers, constructed the Wilson Dam in 1925 at Muscle Shoals, in part to harness the hydroelectric potential of the drop in elevation. This electricity was needed to make nitrate for World War I munitions and, after the war, agricultural fertilizer. The political debate over the ownership of the dam and the future development of the river, however, emphasized the need for a regional approach to its management.

#### DEVELOPMENT OF THE TENNESSEE VALLEY AUTHORITY

To provide the managerial structure for efficient development of the resources of the Tennessee River valley, Congress passed the Tennessee Valley Act in May 1933 as one of President Franklin D. Roosevelt's (1882–1945) innovative and controversial

New Deal programs. This act authorized the formation of a government-sponsored corporation, the Tennessee Valley Authority, or TVA, whose statutory mission was to plan for and carry out “. . . the proper use, conservation, and development of the natural resources of the Tennessee River drainage basin and its adjoining territory for the general social and economic welfare of the nation.” For the politicians, engineers, and managers who helped form the TVA, the organization would allow construction of transmission lines and the provision of electricity at reasonable rates to rural areas not being served by private utilities.

In the early 1930s, only about 10 percent of households outside of cities had electricity. Farmers could not take advantage of modern technologies (such as automatic milking equipment or irrigation pumps), and their ability to store agricultural products under sanitary conditions was limited, which affected the competitiveness of U.S. agriculture. In addition, nonfarm industries were hesitant to build manufacturing centers in areas without reliable and cost-competitive electric service. Privately owned power companies were convinced that farmers in rural areas could not afford and would not use electricity, even if they could profitably build the distribution system to supply it. Although some rural communities formed nonprofit cooperatives to supply electricity, these efforts were largely ineffective because they lacked the technical and financial skills to be successful. As the TVA began to generate significant amounts of abundant, cheap power, first through hydroelectric plants and later using coal, another critical piece of New Deal legislation was passed: the Rural Electrification Act (49 Stat. 1363) of 1936. This act allowed the federal government to make long-term, low-interest rate loans to nonprofit, rural cooperatives that sought to bring electricity to their communities. The act, and its administering body, the Rural Electrification Administration, or REA, provided a stable source of funding to enable development and distribution of electricity to rural areas.

Today, the TVA owns and operates 29 hydroelectric dams, 11 coal-fired steam plants, 16 solar power sites, six combustion turbine plants, and three nuclear power plants. It is the United States's largest public power provider, serving approximately 8.5 million people and 650,000 businesses. The TVA provides electricity at costs that are about 25 percent lower than the national average while maintaining 158 power distributors, 17,000 miles (27,359 km) of power transmission lines, 117,000 transmitter struc-

tures, and 1,025 interchange and connection points across a seven-state region.

### THE KINGSTON PLANT

One of the largest electrical generating stations in the TVA's coal-fired fleet is the Kingston Fossil Plant on the Watts Bar Reservoir of the Tennessee River near Kingston, Tennessee, about 35 miles (56 km) west of Knoxville. From 1955, when TVA commissioned the plant, through the mid-1960s, Kingston was the largest coal-burning power plant in the world. Kingston's nine coal-fired units generate electricity by burning coal to turn water into steam. Under high pressure, the steam is directed to a turbine that spins a generator that produces electricity. Kingston produces about 10 billion kilowatt-hours of electricity a year, enough to power 670,000 homes.

The burning of this much coal results in about 360,000 cubic yards (275,240 cubic m) of by-product or ash. The makeup of coal by-products (ash) is highly dependent on the source of the coal but generally consists of noncombustible minerals such as quartz and other siliceous (silica-bearing) compounds. Toxic heavy metals such as uranium, lead, mercury, and arsenic also can be present in the ash.

Bottom ash that makes up about 20 percent of the residue consists of a heavy, rough mixture of minerals and waste materials that collects at the bottom of the boiler. Fly ash constitutes about 75 percent of the residue and is made up of light, finer particulate present in hot flue gases and trapped by filters and scrubbers. Boiler slag makes up about 5 percent of the residue and is formed when ash melts under intense heat of the combustion process. It typically collects in exhaust stack filters.

Residues (up to 10 percent of the volume of consumed coal) at Kingston are flushed out of the boilers and exhaust stacks and temporarily stored in settling basins. Periodically, these basins are emptied, and many utilities have successful recycling programs for the residues. As an example, there is a thriving market for fly ash as an additive in concrete. Those materials, which have less value (e.g., bottom ash and boiler slag) are removed from the settling basins and placed in a surface impoundment or landfill for permanent disposal. The landfills are usually located near the power plants. Utility company engineers design and construct these disposal units to isolate the coal residues from the environment and minimize the risk of potential negative affects to local surface and groundwater from leachate.

The nine generating units at the TVA Kingston power facility consume vast amounts of coal

and produce corresponding amounts of residues. At normal operating conditions, electric power generation consumes approximately 14,000 tons (12,700 metric tons) of coal per day and produces about 1,000 tons (907 metric tons) of fly ash. Plant operators sluice this fly ash, along with boiler slag and bottom ash, to a settling basin where the residues sink to the bottom. As the basin fills, it is dredged and the ash is moved to one of three dredge cells or compartments within a long-term surface impoundment. Like many coal-burning power plants, the design and construction of ash management impoundments proceeded on almost an ad hoc basis, with the impoundments constructed and expanded as needs for storage capacity increased. At Kingston, residues initially were placed in a 59-acre (24-ha) pond north of the generating units. Surrounding the impoundment were earthen berms or dikes (walls) constructed from soil scraped from the bottom of the pond. As the impoundment grew, horizontally and vertically, TVA engineers used ash, local and imported soil, and other materials to widen and extend the enclosing dikes. TVA did not have a systematic approach to dike design, inspection, or maintenance, and quality assurance controls and procedures typically used during construction of these kinds of high-risk structures apparently were not priority items.

### **COLLAPSE OF WASTE IMPOUNDMENT**

Clarified water from the waste residue flowed from the impoundment into the nearby Emory River through a spillway that is permitted and monitored by the Tennessee Department of Environmental Conservation (TDEC). As the height of the dikes grew, sidewall waste and water pressure increased and small dike failures or blowouts began to occur. In 2003 and 2006, minor slope failures or sloughs took place that led to waste ash escaping from the impoundment. By 2008, the dike walls towered over 80 feet (24.4 m) higher than the Emory River and some 40 feet (12.2 m) above a local, well travelled roadway. In mid-December 2008, the dredge cells covered 84 acres (34 ha) and contained almost 10 million cubic yards (7.6 million m<sup>3</sup>) of coal combustion residues.

Eventually, the hodge-podge system of inadequately designed and constructed dikes could no longer withstand the increasing waste and water pressure from the ever-increasing volume of fly ash and bottom ash that Kingston plant operators were pumping into the impoundments. At about 1:00 A.M. on December 22, 2008, after a period of wet-

ter than normal weather, the dike system along the northern side of the dredge cells failed and catastrophically released approximately 5.4 million cubic yards (4.1 million m<sup>3</sup>) of coal combustion residues. These residues gushed from 50 acres (24.3 ha) of the dredge cells into local streams and onto the land surface. A wave of sludge roiled out of the impoundments, destroying a local roadway (one regularly used by school buses), knocking one home off its foundations, rendering two others uninhabitable, and depositing a several-foot-thick layer of black contaminated ash sludge over approximately 300 acres (121 ha). Fortunately, there were no fatalities or major injuries that occurred as a result of the release, but electrical, gas, and water service was interrupted, a 2,000-foot (610-m) stretch of rail line that serviced the Kingston power plant was destroyed; and more than 40 homes were temporarily evacuated. It was the largest coal ash release in U.S. history.

The TVA responded quickly and effectively to address the disaster. Emergency response procedures activated by the TVA provided alternate housing for affected residents, and they continue to work with homeowners to restore and rehabilitate their land and properties. The TVA also was able to reestablish utility service to the area over the next few weeks and rebuild the damaged rail line. They installed and still operate air, surface water, and groundwater monitoring systems to evaluate and monitor potential public health and ecological effects related to the release, and they share all information with the U.S. Environmental Protection Agency (EPA), the TDEC, and the local community. The TVA has retained a number of outside experts to evaluate short- and long-term impacts to local ecology, including fish and benthic organisms in the Emory River. All of the actions that the TVA has taken in response to this release have been done under the oversight and supervision of the EPA and the TDEC. Cleanup, compensation, and repair costs are expected to be in the tens of millions of dollars and are not likely to be completed until 2012. Even with this response, lawsuits were filed against the TVA by the residents of the area totaling \$165 million, and the EPA declared the release to be an illegal contamination of the river.

The TVA used the Kingston release as the impetus to review and assess coal combustion residue management practices at all of its generating facilities. As a result, significant management and organizational changes have taken place, causing a major refocusing and commitment to safely store and dispose of these materials.

### OTHER EXAMPLES OF RELEASES

Catastrophic releases of waste from residue impoundments have also occurred at other coal-burning power plants in the United States. In 2005, a pipe failure at a generating station in Pennsylvania resulted in the discharge of 100 million gallons (379 million L) of contaminated water and fly ash into the Delaware River. Coal ash residues placed in a former sand and gravel quarry in 2007 and 2008 may have contaminated drinking water wells with heavy metals for almost 100 homes in a Maryland community. In 2009, investigations were under-way in Florida to evaluate whether an ash pile had contaminated a shallow aquifer. Also in 2009, a coal ash release of 4,500 gallons (17,034 L) from a pipeline contaminated a lake in West Virginia. In response to the Kingston and these other coal ash releases, in June 2009 the EPA designated 44 coal combustion residue surface impoundments across the United States as “high hazard,” where a slope or retention wall failure could cause loss of human life, significant economic impacts, and/or major environmental damage. In December 2009, the EPA began a major nationwide review of how coal residues are managed, stored, and disposed.

**Kirkwood-Cohansey Aquifer** The Atlantic Coastal Plain Province sediments underlie the eastern edge of northern Virginia, Maryland, and New Jersey; the entire state of Delaware; and parts of Long Island, New York. The upper unconfined aquifer in southern New Jersey is known as the Kirkwood-Cohansey

Aquifer, the largest aquifer east of the Mississippi River and one of the largest and most productive in the United States. This aquifer contains upward of 17 trillion gallons (65 trillion L) of water underlying 3,000 square miles (7,680 km<sup>2</sup>) of southern and central New Jersey, provides drinking water for 700,000 residents, and even helps to service significant agricultural land in the area. This huge aquifer was considered impervious to water withdrawal and pollution problems that plague other aquifers. Over the years, however, progressively infringing contamination has degraded the water quality over an ever-increasing area, thereby putting both of these claims into peril. The pollution of the Kirkwood-Cohansey Aquifer has now become a major concern of the legislative bodies in all of the areas it serves.

### STRATIGRAPHY OF THE AQUIFER

The Atlantic Coastal Plain sediments began to be deposited in the Cretaceous period about 70 million years ago as the Atlantic Ocean began to open in earnest. The rapid growth of this basin submerged the shorelines and initiated a period of semicontinuous sedimentation that continues today. The early deposition was erratic, with many different environments producing many different kinds of sediments. The low energy of the system in several areas allowed the deposition of a number of thick clay units that were mined in the late 19th and early 20th centuries for ceramics. The first dinosaur bones ever found in North America were in one of these units in New Jersey. Once the ocean basin became wide enough, clean beach sand began to be deposited similarly to the current situation. The only breaks in the sand deposition were from retreats of the ocean during ice ages. At those times, the sea level dropped up to 200 feet (60 m), exposing the deposited sediments to erosion and reworking in terrestrial systems. These periods of sea level retreat are marked by confining clays and phosphate-rich layers called green sands. The clean sand that was deposited on the beaches during times of normal sea level makes the best aquifers because it can store and transmit groundwater better than the other units. The Kirkwood-Cohansey Formations that constitute the Kirkwood-Cohansey Aquifer are composed of beach sand sediment. This unit is more than 6,500 feet (2,000 m) thick at its eastern edge but thins out to 0 feet westward.

### WATER PRODUCTION FROM THE AQUIFER

The water from the unconfined Kirkwood-Cohansey Aquifer has been historically considered the cleanest

available. The surface through which surface water enters the groundwater system, known as the *recharge zone*, includes the protected Pine Barrens of southern New Jersey, which contains extensive wetlands that filter the water both chemically and biologically. The water has been historically regarded as so clean and plentiful that in the late 19th century, the city of Philadelphia, Pennsylvania, attempted to commandeer it for its own use. The state of New Jersey stepped in at the last minute to prevent the plan from being executed. The aquifer has outstanding porosity and permeability in the clean beach sand. High-capacity production wells used for public drinking water supplies commonly yield 500–1,000 gallons (1,900–3,800 L) per minute, and many exceed 1,000 gallons (3,800 L) per minute with an apparently unlimited supply. It is estimated that about 200,000 private wells draw water from the Kirkwood-Cohansey Aquifer.

### WATER QUALITY AND POLLUTION

The once-enviable water quality of the Kirkwood-Cohansey Aquifer has degraded appreciably in recent years, and there have even been several health scares as a result. In general, water quality is considered satisfactory except for several local excessive iron concentrations. In these areas, the water must be treated in a water softener; otherwise, clothes and appliances, among other items, will be stained red. In some coastal areas, the unconfined Kirkwood-Cohansey Aquifer system experiences brackish or saltwater incursion into the freshwater supply. This incursion has been steadily increasing with the combination of increased water usage and sea level rise. The water is also very acidic with no material available to buffer it. It can be very corrosive to pipes, water-bearing appliances, and pumps, among others.

There is also significant anthropogenic pollution that is progressively degrading the Kirkwood-Cohansey Aquifer to deeper levels. The naturally occurring acidic groundwater in much of the aquifer has a low enough pH to extract lead from plumbing, producing unacceptably high levels in the drinking water in a number of homes. The acidity is the result of excess  $\text{SO}_4$  ion concentrations in the water. There are also numerous pollutants from agricultural activities that yield elevated concentrations of  $\text{NH}_4$ , B, Cl, and  $\text{NO}_3$  ions in groundwater. These, in addition to the acidity, can dissolve naturally occurring radium and mercury in some of the geologic units. High radium concentrations in the Kirkwood-Cohansey Aquifer system were found to exceed the maximal contaminant level in 33 percent

of 170 wells tested and estimated to affect as many as 200,000 private wells in six New Jersey counties. These high radium contents are associated with low pH and high nitrate concentrations. High radium levels in wells from agricultural areas are associated with recharge of agricultural return flows, which induces nitrification and reduces pH. Such a combination enhances the extraction of radium from clay minerals and consequently increases the radium levels in the associated groundwater. Mercury appears to be elevated in groundwater by the same process, and about 600 domestic wells were found to exceed the maximal contaminant level (MCL) set by the U.S. Environmental Protection Agency.

Not all of the inorganic pollution problems are related to extraction from natural sources. In Vineland, New Jersey, there is an arsenic plume from a pesticide factory that is the longest traveled in the world. The arsenic enters the groundwater system from the industrial site and is transported tens of miles to a stream, eventually reaching the Atlantic Ocean. The high permeability of the aquifer, in this case, is detrimental to the environment.

Organic pollutants were also found to be elevated in many of the wells that penetrate the Kirkwood-Cohansey Aquifer. In a recent study, chloroform, methyl tert-butyl ether (MTBE), trichloroethane (TCA, TCE), tetrachloroethylene (PCE), and carbon disulfide were detected frequently at low-level concentrations in a network of 78 shallow wells in the surficial Kirkwood-Cohansey Aquifer system. Considering the number of Superfund sites within the aquifer, this is not surprising. The Naval Weapons Station Earle site in Monmouth County, New Jersey, is a Superfund site that is situated in the recharge area of the Kirkwood-Cohansey Aquifer system. This project is attempting to address the paints and paint thinners, solvents, varnishes, shellac, acids, alcohols, caustics, pesticide, herbicide, rinse water, live and spent ordinance, and fuel that were regularly dumped there for a number of decades. The Iceland Coin Laundry Area Ground Water Plume is a regionally extensive TCE Superfund site in Vineland, New Jersey. Operations at the Fort Dix military facility included dumping volatile organic compounds (VOCs), semivolatile organic compounds (SVOCs), and metals into the ground, which also contaminated the water in the Kirkwood-Cohansey Aquifer. The area is also now a Superfund site. The Price's Pit Superfund site, which includes virtually every major organic and inorganic pollutant possible, also affects the aquifer, though not directly.

# L

**landfill** The largest human structure by volume ever built is not the pyramids or a stadium; it is the Fresh Kills Sanitary Landfill. This huge heap of garbage on Staten Island, New York, is 146 feet (45 m) high and 146 feet (45 m) deep and covers an area of 296.5 acres (120 ha). Landfills have existed in

and around cities for thousands of years. The first documented municipal waste dump is believed to have been established around 500 B.C.E. in Athens, Greece, but waste dumps were used on a local basis far before then. Simple landfills, known as dumps, historically were called middens and were either

Active landfill in western Washington State (Doug Wilson/Alamy)

public or private. In dumps, refuse of all sorts has been simply dumped on the surface and allowed to degrade with time. Town or municipal dumps were specific sites where refuse was disposed of in areas where there was a significant population. In rural areas, dumps of household refuse were located in a convenient place on the property, commonly behind an outbuilding or rock wall. Depending upon the composition of the refuse, they ranged from little more than an eyesore and a possible physical hazard to a serious threat to public health and a breeding ground for vermin. In 1976, the U.S. Congress passed the Resource Conservation and Recovery Act (RCRA), which required that all dumps be converted to sanitary landfills. In modern terms, landfills are either municipal or hazardous waste types.

Although RCRA was the most significant step in the history of landfills, there was other legislation as well. In the 1940s and early 1950s, the vast amounts of waste being generated at an industrial and at a public level began to become a problem. In response, the issue was investigated by the federal government. In 1953, a committee of the U.S. Public Health Service (USPHS) and the American Public Works Association (APWA) published recommended guidelines for refuse collection and disposal practices for a small community. The guidelines were just recommendations for states and were not enforceable regulations. In 1961, the USPHS developed a set of recommendations of standards for sanitary landfill operations to be enforced on a state-by-state basis. In 1965, with the passage of the Solid Waste Disposal Act, the USPHS accelerated its efforts to incorporate sanitary landfill practices into waste repositories within the United States. When the U.S. Environmental Protection Agency (EPA) was created in 1970, the solid waste program was moved from the USPHS to its jurisdiction. It took several years of lobbying to gain support for the sweeping changes of RCRA in 1976 but none as difficult as changing from an advisory to a regulatory status. Even then, full regulatory authority over landfills and direction of the preparation of landfill criteria were not granted until Congress passed the 1984 RCRA Hazardous and Solid Waste Amendments. The EPA responded with a very complete set of criteria known as Subtitle D for adoption by the states.

### PLACEMENT OF LANDFILLS

Finding a suitable location for the placement of a landfill is usually an arduous process. Residents of an area rarely want a landfill near their property because they fear the degradation of quality of life from the odor and stigma and reduction in their

Edgeboro landfill in East Brunswick, New Jersey, ca. 2001  
(AP Images)

home and property value. This issue has been called the “not in my back yard” syndrome. A debate typically ensues that pits irate residents against legislators, and it can escalate into a real battle. This sort of political battle can rage on for years and can impact the more important issue of the physical constraints on the location, which involve both geology and topography. Landfills must be set in lots that are large enough to contain the entire landfill and all the monitoring and administrative facilities, be well removed from populated areas, and yet be close enough that transportation costs do not become prohibitive. They cannot be on hill-tops or steep slopes because these areas can be physically unstable. They cannot be in wetlands or anywhere in which they might impact the water table. The waste and leachate generated by landfills can pollute the water supply and do significant damage to the ecology. This causes further debate because surface depressions are really the best features for containment and yet as such are closer to the water table. It is best to have a ready source of soil to cover the waste, so fresh bedrock surfaces are also undesirable. Finally, certain rock types are not ideal even though they are commonly used

as landfill sites. Limestone, for example, develops karst topography, which includes cave systems, the roofs of which can collapse into a sinkhole. If a sinkhole forms beneath the landfill and collapses, the results could be disastrous, especially if in a hazardous waste landfill. Water supplies in the area could be severely damaged. Unfortunately, in some areas, Florida, for example, there is no choice but to site landfills on limestone.

### MUNICIPAL LANDFILLS

Most cities operate municipal landfills to dispose of their solid waste. By 1996, 60 percent of all solid waste was disposed of in landfills, while 20 percent was incinerated, and 15 percent was recycled. At that point, there were 75,000 on-site industrial landfills, 5,800 municipal landfills, and more than 40,000 abandoned municipal landfills. In municipal landfills, solid waste is dumped into an excavated opening or pit that is lined with a chemically resistant plastic or rubber liner and compacted

by heavy equipment before it is covered with a minimum 6-inch (10-cm) thickness of dirt on a daily basis. Collection pipes are installed below and above the landfill to remove leachate in some, while others are judged to require being underlain by soil and rock to purify the water sufficiently before it enters the water table. Another sheet and/or a thick impermeable clay cap covers the landfill after it is full to prevent the infiltration of rainwater from above. Infiltrating rainwater could dissolve the waste to form leachate that could enter the groundwater system through a leak in the liner, or, if it filled up with water, it could overflow. The surface is formed into a mound to drain runoff away from the landfill, and a final soil cover of 24-inch (40-cm) thickness, which is covered with vegetation to stabilize the soil and slope, absorbs minor rainfall. Vertical wells are drilled into the landfill, and pipes are installed to vent methane gas produced by biogenic decay of the organic waste. Some communities mine the methane and sell it to local utility companies. Finally, monitoring wells

**Illustration of a secure landfill for toxic and hazardous waste: Drums of waste are kept upright and intact, and an extensive full-time monitoring system ensures against leaks.**

**Illustration of municipal sanitary landfill methods in which waste is covered with soil on a daily basis, ultimately filling an excavated pit**

are drilled around the landfills to test the quality of groundwater on a regular basis. If raw leachate reaches the water table, it can contaminate the local water supply with both pollutants and disease.

### HAZARDOUS WASTE LANDFILL

Disposal of hazardous waste is much more highly regulated than disposal of municipal waste. Landfills for hazardous waste must be lined with a thick, chemically resistant, and impermeable geotextile-plastic liner, thus preventing any leachate from escaping. All leachate is removed from the base of and below the landfill by means of a collection pipe to a storage and/or treatment facility. Hazardous waste is not compacted but, instead, carefully placed in the landfill and lined top and bottom. Rock and gravel are used to stabilize the waste to prevent it from being knocked over or crushed by overlying layers. The top is similar to that of the municipal landfill but must include an impermeable sheet, as well as a thick clay cap. There are typically more monitoring wells in a hazardous waste landfill, and they are sampled on a much more frequent basis. Hazardous landfills are built to last tens to hundreds of years.

Hazardous waste landfills can be filled with industrial chemicals, pesticides, some radioactive waste, some biological waste, and, in some cases, military refuse. The materials are deemed extremely dangerous to both human health and the environment and are highly regulated. In some cases, they are regulated on a national security level. These are commonly disposed of separately from commercially produced chemicals. Even the placement of the materials into the landfill must be performed under strict guidelines with proper tolerances and with workers' wearing specified protective clothing.

**Launch Complex 34 Cape Canaveral, Florida 1961–1971 Soil Pollution** Construction began on Launch Complex 34 in Cape Canaveral, Florida, in June 1959, and the facility was placed into service January 1962. Four *Saturn I* and *Saturn IB* rockets were tested and launched from this complex between 1961 and 1968, and it supported the Apollo and Skylab space vehicle programs. One of the more unique launches that took place from Launch Complex 34 was an experiment known as Project Highwater. The primary objective for this launch was to assess how liquid fuel would behave during lift-

off and orbiting maneuvers. Some 23,000 gallons (87,065 L) of water was loaded onto dummy second- and third-stage rocket boosters, and National Aeronautics and Space Administration (NASA) engineers and designers gathered important data on how the liquid payload shifted and moved during launch. At the height of its flight, 104 miles (167.4 km) above the Earth, the rocket was detonated and released the water into the ionosphere. Scientists had hoped to gain information on the formation of clouds and ice particles at this altitude, but a malfunctioning telemetry system made the data unreliable.

*Apollo 7*, the first manned Apollo flight, lifted off from Launch Complex 34 at Cape Kennedy on October 11, 1968. Launch Complex 34 also is where, on January 27, 1967, the tragic *Apollo 1* fire took the lives of three other Apollo program astronauts. Launch Complex 34 was decommissioned in 1971 but, because of its prominent role in the space program, was declared a national historic landmark in 1984 and is a popular stop on the Cape Canaveral bus tour.

### POLLUTION OF THE SITE

Cleaning and degreasing of precision equipment associated with space flight required the use of extensive amounts of chlorinated solvents. During the 1960s and continuing until the advent of modern environmental management practices in the late 1970s and early 1980s, spent solvents from these operations, primarily trichloroethene (TCE), were often inadvertently and sometimes intentionally discarded or spilled directly onto the soil on and around the launch complex. At Launch Complex 34, the spent TCE was discharged into drainage pits or onto the ground, both near the launch pad and from the Engineering Support Building (ESB). Since then, an estimated 45,000 pounds (20,412 kg) of TCE has migrated into approximately 6 million cubic yards (4.6 million m<sup>3</sup>) of soil at the launch complex and is contaminating the underlying groundwater.

Like many industrial solvents, TCE and its breakdown products 1,2 dichloroethylene (DCE) and vinyl chloride are less viscous and have a density greater than water. If released into the environment, they tend to move downward through the soil and groundwater, coming to rest on layers of low-permeability silt and clay or rock. This subsurface layer or pool of accumulated TCE is a type of dense nonaqueous-phase liquid (DNAPL). DNAPL is very difficult to locate and remediate, as its presence is controlled not so much by the groundwater flow system near where it was released, but rather through variations in subsurface soil conditions, such as porosity, permeability, and layering, which can be

**Injection of potassium permanganate into contaminated groundwater at Launch Complex 34, Cape Canaveral Air Station (NASA)**

difficult to predict and locate. DNAPL can act as a source of groundwater contamination for many years after its release has occurred, slowly dissolving into the water of the aquifer.

Another environmentally challenging characteristic of this compound is that it does not readily biodegrade. The very large size of the TCE molecule and the presence of chlorine tend to inhibit bacterial breakdown and allow TCE to persist in the environment for long periods. Also, TCE does not tend to attach to organic matter that may be present in the subsurface. This means that TCE will migrate at about the same rate as groundwater, whereas other contaminants often move much more slowly through the subsurface. TCE is toxic and, if inhaled, affects the central nervous system, causing dizziness and drowsiness and, at high concentrations, potential fatalities. The U.S. Environmental Protection Agency (EPA) has classified TCE as a probable human carcinogen. Ingestion of large amounts of TCE may lead to liver damage, kidney malfunction, and cardiac arrhythmia. Similar health effects have been observed from exposure to DCE and vinyl chloride.

### THE CLEANUP

TCE was found in the soil of Launch Complex 34 at concentrations up to about 0.03 percent (30,000 mg/kg), essentially present as a separate phase or DNAPL. TCE cleanup is complicated by two factors, the role Launch Complex 34 (LC-34) has had in the history of the space program and the need not to interfere with other, nearby NASA activities. It is a designated historic structure, and remediation must be carried out in a way that minimizes changes to the characteristics of the building, the site, and the local environment. This means that remediation cannot destroy historic materials, and chemical or physical techniques such as sand-blasting or large-scale excavation that might damage the historic materials cannot be used. In addition, although NASA is no longer using LC-34 for flight operations, the surrounding area is an active spaceport, and remedial actions cannot interfere with access to the area. In situ chemical oxidation using potassium permanganate was one of the technologies chosen by NASA, in cooperation with the state of Florida and the EPA, to clean up this contamination within the context of the site.

In situ chemical oxidation is a remedial process that introduces an oxidant into the subsurface to break down or convert the contamination into a more stable, less toxic form through oxidation. In this process, oxygen removes electrons from other atoms. This tendency is so strong that it has led chemists to name any process that entails the loss of electrons from an

atom or ion oxidation, even those that do not involve oxygen. In terms of environmental remediation, if an oxidizing agent is mixed with the contaminant in soil, then the subsequent chemical recombinations that take place as electrons are removed by the oxidant would destroy or break down the contaminant. In practice, the contaminants are actually converted to more stable, less mobile, or inert compounds or readily biodegradable organic fragments. The three most common chemical oxidants used in soil remediation are ozone, peroxide, and permanganate.

Ozone ( $O_3$ ) is a very aggressive oxidant. If ozone is introduced into the vadose zone as a gas, it reacts quickly with the contaminant mass. The contaminant, usually a petroleum hydrocarbon, is converted to carbon dioxide and water or is broken down into carbon and other compounds that surrounding bacteria can utilize. A liquid peroxide solution can also be used to initiate chemical oxidation in the subsurface to remediate polluted soil. Typically, the peroxide is introduced in a water mixture through specially designed injection wells. In order to accelerate the peroxide's chemical oxidation effectiveness, a metal catalyst, most commonly iron, is added. This peroxide and iron mixture is known as Fenton's reagent. The hydroxyl radicals are strong oxidizing agents, capable of rapidly attacking and breaking the carbon chemical bonds of most organic compounds, usually within minutes after its application. As in ozone-induced chemical oxidation,  $O_2$  is released during peroxide decomposition and can help encourage bioremediation.

Permanganate can oxidize contaminants under a wide range of pH (3.5–12) and does not require a catalyst. Its oxidation potential is lower than that of Fenton's reagent by about 40 percent, and, therefore, permanganate requires more time to act. Potassium permanganate ( $KMnO_4$ ) is most commonly used, but Na, Ca, or Mg varieties are also available. The main advantage of permanganate is that it is not as reactive as ozone or Fenton's reagent. The permanganate can move deep into the contaminant mass, especially in low-permeability formations such as clay or silt, and contact a larger amount of impacted soil. Permanganates are also more easily handled and, because of their high solubility, simpler to mix and inject into the subsurface.

The permanganate ion is preferentially drawn toward the electrons in carbon-carbon double bonds found in compounds called alkenes. Examples of alkenes include trichloroethylene (TCE) and tetrachloroethylene (PCE). The permanganate breaks down the double carbon bonds by borrowing the electrons from the carbon atoms. Once the double bonds are broken, the unstable fragments are converted to carbon dioxide through

## Space Shuttle Launches and Air Pollution

The Saturn V rocket, the largest ever built and operated by the National Aeronautics and Space Administration (NASA), successfully launched the Apollo Moon missions and the Skylab Space Station, and it continues to lift the space shuttle into orbit around the Earth. When the fuel in the Saturn V is ignited, it forces a massive, continuous thrust of hot gases downward through its vents and portals. This downward force results in an equal and opposite push of the rocket upward. Current space vehicles operate on a linear, multistage design. A single-stage-to-orbit (SSTO) vehicle that is being evaluated by NASA can achieve orbit without discarding fuel tanks or motors. SSTO vehicles, which also would be reusable, may be less expensive to launch and operate, although more expensive to design and build.

### TYPES OF ROCKET FUEL

The rockets and their fuels are stacked on top of each other, with the first stage the largest and having the heaviest fuel. When the first-stage rocket's fuel is exhausted, it is detached with a small explosive charge from the space vehicle, and the second-stage rocket is fired. After the second-stage rocket's fuel is used up, the third stage is fired, and so on. By jettisoning the empty fuel tanks and associated rocket motors, the now much lighter spacecraft requires less fuel to reach its mission or orbital velocity and altitude. In addition, fuel selection can be optimized for its operational atmosphere.

The power, efficiency, and environmental impact associated with the use of rocket fuel are dependent upon its chemical composition. NASA, the military, and commercial launch organizations generally rely on four types of propellants:

#### Petroleum

This type of rocket fuel is highly refined kerosene called RP-1 (refined petroleum). Rocket fuels need to provide their own oxidizer, and RP-1 is usually combined with liquid oxygen (LOx) and burned to create thrust at low altitudes. RP-1 is a fossil fuel, and its combustion products include carbon dioxide, sulfur and nitrogen oxides, and particulate matter.

#### Cryogenics

These types of propellants are a mixture of fuel of liquid hydrogen (LH<sub>2</sub>) and liquid oxygen. Both components are liquid at only very low temperatures (hundreds of degrees below zero), but cooling and compressing them

allow large amounts to be stored in appropriately sized containers. If they were left in their gaseous forms, huge fuel tanks would be needed to store sufficient amounts of hydrogen and oxygen to launch a spacecraft or missile. Cryogenic fuels are lighter and have about 40 percent more power by weight than petroleum or solid rocket fuels. The Saturn V second- and third-stage rockets are cryogenically fired and are used to insert the space shuttle into Earth orbit. The end product of this combustion process is water, making cryogenic fuel very environmentally friendly.

#### Hypergolics

Thrust from this type of propellant occurs as fuel of monomethyl hydrazine (MMH), or hydrazine, and oxidizer of nitrogen tetroxide (N<sub>2</sub>O<sub>4</sub>) ignite during mixing, requiring no ignition source. One of the major advantages of hypergolics is that they can be stored at ambient temperatures and pressures, and the reaction can be started and stopped by simply shutting off the flow of either the oxidizer or the fuel. MMH and N<sub>2</sub>O<sub>4</sub>, however, are dangerously toxic and must be managed by using highly controlled safety procedures. Hypergolics power the space shuttle's orbital maneuvering, attitude control, and reentry systems.

#### Solids

Also called solid rocket boosters (SRB), these are the oldest type of rocket fuel, first developed in ancient China. Fuel and oxidizer are loaded into a steel shell and ignited to provide thrust. For the Space Shuttle, the oxidizer is ammonium perchlorate, and the fuel is a form of powdered aluminum. A third ingredient, polybutadiene acrylic acid acrylonitrile, binds the mixture. Initially a liquid, SRB is cured into a soft, rubberlike solid. Stable and easily stored, SRBs do not require complex propellant-feed systems and often are used to provide additional thrust during launch or during the final stages of a launch. The space shuttle uses the largest solid rocket motors ever built, with each reusable booster containing more than 1 million pounds (454,000 kg) of propellant, supplying almost 2.7 million pounds (1.2 million kg) of thrust. The majority of military rockets (intercontinental ballistic missiles [ICBMs] such as the Minuteman and Peacekeeper) also use solid rocket fuels.

### ENVIRONMENTAL EFFECTS OF ROCKET LAUNCHES

Space shuttle launches as well as other types of space exploration or military rocket testing and develop-

ment produce adverse environmental effects. Most of the emissions that are seen during a space shuttle launch are water vapor or steam mixed with very minor amounts of combustion products. At 11 seconds before the main engines fire, a storage tower near the launch pad begins to discharge about 900,000 gallons (3.4 million L) of water from six large nozzles, called rainbirds, into a trench just beneath the launch pad. This water continues to flow for about 20 seconds after main engine ignition and acts as an acoustical barrier and flame deflector, protecting the shuttle from the noise and heat generated by the SRBs during a launch.

The exhaust gases from the SRBs, which provide about 70 percent of the launch thrust for the space shuttle, contain very small amounts of chlorine. This chlorine combines with water vapor to form hydrochloric acid mist, which has caused some damage to wetlands and plants near the launch pad. NASA tries to mitigate these effects by launching when local winds blow this mist out to sea, where it is quickly neutralized by seawater.

As the space shuttle climbs into orbit, exhaust gases released into the thermosphere, the outermost layer of the Earth's atmosphere, settle and condense into a cloudlike layer of ice crystals. This layer, which has been detected in the sky over the Arctic, results in a "night-shining," or noctilucent, cloud, one that is not visible until the Sun's rays reflect off it from below the horizon. Although this small amount of additional water vapor is not likely to have an impact on either arctic or worldwide atmospheric conditions, its presence is illustrative of the need to be alert to the environmental consequences of rocket launches.

Of more immediate concern is perchlorate, one of the primary components of SRB fuel. Perchlorate has been detected in groundwater and soil samples from more than 40 states. If ingested, perchlorate interferes with iodine uptake in the fetus, young children, and adults. The U.S. Environmental Protection Agency (EPA) is currently considering adding perchlorate to the list of chemicals that must be tested under the Safe Drinking Water Act. California, Arizona, Nevada, and other states that have hosted significant amounts of rocket tests and launches are especially concerned over the presence of this compound in their local environments and perchlorate's potential impact on public health.

On a global scale, about 11,000 tons (10,000 metric tons) of rocket propellant is burned in the atmosphere annually from both civilian and military sources. The release of chlorine, free radicals, and aerosols as a result of these launches, particularly those using SRB

and hypergolic fuels, may damage the ozone layer. Although the amounts of potentially ozone depleting substances released by this activity are relatively small on an international scale, approximately 130,000 tons (117,900 metric tons) of ozone-depleting products was manufactured worldwide in 2003. They are, therefore, not insignificant, and part is delivered directly to the stratosphere, where they do the most damage.

The technologies to launch rockets into space were developed at a time when political and military agendas were the driving forces. Technological dominance over the Soviet Union far outweighed the environmental consequences on the American agenda. Those attitudes have changed in recent years, and space exploration is becoming more environmentally responsible. Environmental Impact Statements are required before a new or expanded launch program can be initiated, and these programs must include measures to reduce or minimize ecological and atmospheric effects. Extensive research is being done to find a cheaper, safer, and less environmentally damaging replacement for hydrazine-driven thrusters. Ion engines and electric propulsion systems are the leading candidates, along with short-term fuel combination changes that provide some environmental benefit from the more efficient mixing and matching of propellant types.

—by Robert P. Blauvelt

either hydrolysis—decomposition that occurs when water molecules are taken up into the fragment—or further oxidation by the permanganate ion.

Regardless of which oxidant is used, it must be chosen on the basis of the type and extent of contamination as well as cleanup goals and overall site conditions. All the compounds are very reactive and must be handled with great care to prevent injury to workers or nearby residents. Oxidants by their nature are corrosive and can wear away or dissolve dispensing equipment. Site-specific procedures for their safe distribution must be developed and strictly followed. Chemical oxidation can generate enough heat to boil water, so in some cases provisions must be made to collect and treat the gases that may be given off by the process. Hazardous intermediate compounds can form if not enough oxidant is added to the contaminant mass or if other compounds in the soil such as organic matter consume the oxidant before it can completely react with the contaminant. These issues aside, chemical oxidation is rapidly gaining favor as a remedial technology because it can efficiently reach and clean up contaminated soil in time frames much shorter than many other methods required.

At LC-34, the area of contaminated soil to be treated was divided into a cell 50 feet (15.2 m) wide by 75 feet (22.9 m) long by 45 feet (13.7 m) deep. Samples collected within that area indicated that an estimated 13,420 pounds (6,100 kg) of TCE was confined to three soil layers: an upper sand unit; a middle, fine-grained sand unit; and a lower sand unit. In order to develop final design parameters, a pilot test using a tracer solution (sodium fluoride) mixed with 2 percent permanganate was first tried. This test allowed the design engineers to obtain data on the way the permanganate solution would move through and react with the contaminant mass. The full-scale treatment program utilized 19 injection wells, which were driven into the various layers within the designated treatment zone or cell, and more than 150,000 pounds (68,039 kg) of permanganate at concentrations ranging from 0.2 to 3 percent was injected in three phases over 61 days.

After treatment, soil samples were collected from each of the three layers, and TCE levels were tested. Posttreatment soil sampling data indicated that the mass of TCE within the cell had declined by 82 percent.

**leachate** Fluid rich in by-products of the decomposition and dissolution of municipal and/or toxic waste is generically termed leachate. The putrid, foul-smelling liquid that drips from the back of a garbage truck is analogous to leachate but typically far less dangerous than landfill leachate. Any fluids that are emitted by waste, whether by infiltration and dissolution or directly derived from the waste, is leachate. The toxicity of leachate depends upon the type of waste involved. Hazardous waste landfills produce much more dangerous leachate than municipal landfills. Pipes are carefully installed into landfills to remove the fluids from the bottom. They are then put through an ex situ remediation process and returned to the groundwater system or removed completely, depending upon the toxicity.

If leachate enters the groundwater system through a hole in the bottom of a landfill, it can severely degrade the quality of the groundwater. In this case, a full-scale remediation project must be initiated. This involves the drilling of monitoring and recovery wells and construction of water treatment facilities at significant cost. Depending upon the waste in the landfill, patching the liner or removing waste may have to be performed as well. Although leachate may contain inorganic pollutants, it is primarily a biological process that produces organic waste.

#### FORMATION OF LEACHATE

There are three stages in the formation of leachate from municipal sanitary landfills, which are by far the major source of leachate. The first stage is aerobic decomposition, in which all of the available oxygen present in the waste is consumed. These chemical reactions are exothermic, and the temperature of the landfill increases. The second stage in this process is called the acetogenic stage. Anaerobic bacteria break down the waste by fermentation of sugars to acetic and other volatile fatty acids. Car-

**Cross-sectional (top) and map (bottom) view of a leaking landfill producing leachate that enters the groundwater system and forms a contaminant plume spreading in the direction of groundwater flow**

bon dioxide and hydrogen gas are produced, and alkalinity of the fluid is greatly increased. Later, sulfate-reducing bacteria cause biodegradation of the fatty organic acids. The formation of acids causes dissolution of waste materials and increases the content of inorganic pollutants in the leachate. The final stage in leachate evolution is called the methanogenic stage. After all the sulfate is consumed, microorganisms that produce methane and carbon dioxide from volatile fatty acids and other organics become dominant. In this stage, methane can be mined from the landfill for commercial uses. Eventually, the decomposition rates decrease as the amount of available organic material decreases and the landfill slowly becomes inactive.

Leachate composition varies considerably depending upon the type of waste, age of the landfill, climate, precipitation, integrity of seals, and other factors. The organic content of the leachate is expressed in

BOD (biochemical oxygen demand) and COD (chemical oxygen demand). These parameters reflect the amount of oxygen needed to oxidize the organic matter by microbial biodegradation (BOD) and chemical oxidant (COD).

**lead** Lead is an inorganic heavy metal that is consistently one of the pollutants of greatest concern in modern society. On the 2007 CERCLA Priority List of Hazardous Substances, lead is ranked the second most dangerous pollutant, with only arsenic ranked higher. It is not only the severe adverse health effects caused by lead but also its immense distribution in the environment that gives it such a high ranking. For example, lead has been found in at least 1,272 of the first 1,684 U.S. Environmental Protection Agency (EPA)-designated Superfund sites on the National Priority List. This is probably the highest percentage of any of the dangerous pollutants.

Considering the vast usage of lead in society into the 1970s, it is surprising that it is now so vilified. Lead was used as a gasoline additive, as a paint additive, in virtually all plumbing (the term *plumber* means “worker of lead”), in all automotive batteries, in all bullets and other projectiles, and in many electric and electronic devices among many other uses. Through all these applications there was barely an American who was not exposed to lead in a significant way, and the ambient levels of lead that people were exposed to on a daily basis were orders of magnitude above natural background levels. Perhaps even more surprising is that historical examples suggest that people knew that lead has detrimental effects. One of the often-cited contributing factors to the fall of the Roman Empire was the excessive use of lead in plumbing and food. Lead poisoning on a societal level may have so weakened the health of the citizenry that they were unable to defend themselves against attack.

### PROPERTIES, USES, AND PRODUCTION

Lead is a naturally occurring inorganic element commonly found in minerals, soils, and mineral deposits throughout the world. In the United States, currently some 88 percent of all lead is mined from seven mines in the New Lead Belt of southeastern Missouri. There is a long and varied history of lead use in the United States. The earliest widespread

use of lead that affected the environment may have been in paint, beginning in the early 19th century, when lead carbonate or “white lead” was used as the paint pigment and primary component, right through the 1960s. Before 1955, lead constituted up to 50 percent of the volume of white paint but the level was voluntarily reduced by some manufacturers thereafter. Lead orthoplumbate and lead oxide, or “red lead,” were used as red, pink, and orange pigment, most commonly for primers, also through the 1960s. In houses built before 1978, some 83–86 percent contain lead paint. Ever since there was indoor plumbing, lead has been used as solder and even in pipes in the past. In the 1920s, as cars began to become more sophisticated, lead was used as an additive to gasoline to boost octane and prevent knocking. It became by far the greatest source of lead emissions, providing up to 90 percent of environmental exposure in many areas. Lead is currently the fifth most consumed metal in the United States. Approximately 85 percent of lead is produced domestically and 40–50 percent is from recovery and recycling efforts. The United States is the world leader in lead recycling efforts. In 2006, mine production was 473,000 tons (430,000 metric tons), and the five-year average is 486,600 tons (442,400 metric tons). Primary lead from refineries was 148,500 tons (135,000 metric tons), which indicated a steady decrease from 2002, when production was 288,200 tons (262,000 metric tons). Scrap recycling produced 1.24 million tons (1.13 million metric tons) of lead in 2006. The two most important consumers of lead are lead-battery producers and radiation shield producers. Lead-acid batteries account for 83 percent of the consumption. Other uses in outdoor sports and recreation, hobbies, and wheel balancing weights are minor.

### ENVIRONMENTAL RELEASE AND FATE

Currently, sources of environmental lead include both industry in localized areas and widespread residential sources. Some 144 million pounds (65.5 million kg) of industrial lead was released into the environment from 1987 to 1993, primarily from lead and copper smelting and steelworks; lesser sources include batteries, plumbing fixtures, iron foundries, and copper mining. The states with the highest releases are, in decreasing order, Missouri, Arizona, Montana, Utah, Texas, Ohio, Indiana, Tennessee, Illinois, Wisconsin, Minnesota, and New Mexico. Only Ohio and Indiana had significant releases into surface water. Much more widespread sources of environmental lead are corrosion of lead plumbing (especially in older homes), both

interior and exterior peeling paint in older homes, paint-tainted soil surrounding older homes, glazing on ceramic stoneware, dyed and printed paper and incineration thereof, and aluminum cookware from countries lacking environmental controls. Many hobbies and household chores can also expose people to lead including hunting and fishing (shot and sinkers), home renovation (paint, pipes), furniture refinishing, ceramics and pottery, glass work (leaded glass, stained glass), and auto restoration, among others. Other minor sources of lead exposure are the consumption of vegetables grown in lead-tainted soils, wine and some alcohol, and cigarette smoking.

Most lead in the environment is from atmospheric sources and settles to the ground and surface water as nonpoint source pollution. It binds tightly to soils in the upper 1 to 2.5 inches (2–5 cm) and does not migrate to groundwater under typical conditions ( $> 5$  percent organics,  $\text{pH} > 5$ ). Remediation of soil is typically accomplished by removal. In the subsurface, some anaerobic microbial activity may be a significant source of dissolution, thereby increasing the lead content of groundwater. Metallic lead exposed at the surface

is degraded by oxidation and hydration, but, under certain conditions, silicate and carbonate films can protect it from chemical alteration. It can contaminate surface water but tends to bind to clay and organic particles, ultimately settling into the sediments. Some microorganisms in lake sediments can methylate some inorganic lead compounds. Highly acidic surface waters and groundwaters can contain significant amounts of lead, and methylation can also increase concentrations. Dredge spoils can also be contaminated with lead. There is little bioaccumulation of lead in fish (bioconcentration factor 1.65), and it does not accumulate in the edible parts of the fish, but shellfish can contain lead (bioconcentration factor 3.4).

### HEALTH EFFECTS FROM EXPOSURE

Acute lead poisoning results in nausea, sluggishness, vomiting, painful gastrointestinal irritation, diarrhea, loss of appetite, colic, weakness, dehydration, discoloration of the lips and skin, convulsions, external limb paralysis, coma, and death with increasing exposure. Chronic exposure to lead results in numerous adverse physiologic effects including

Peeling lead paint at abandoned mental institution in Traverse City, Michigan, 2004 (© Robert Sciarrino/Star Ledger/Corbis)

neurological effects, renal damage, hematological problems, endocrine effects, cardiovascular and hypertension effects, reproductive effects, developmental problems, and cancer. The health effects of lead exposure in children are so devastating that the Center for Disease Control established a class system of poisoning with recommended treatments. The nervous system is the primary area of damage from lead, and children are much more readily affected than adults. Symptoms include lower than average IQ test scores, attention deficit hyperactivity disorder (ADHD), muscular tremor and weakness, loss of memory, depression and mood swings, decreased reaction time, irritability, decreased hand-eye coordination, hearing impairment, and early onset of Alzheimer's disease. Lead also readily affects the kidneys, resulting in impairment of proximal tubular function, chronic nephropathy, gout, and ultimately kidney failure if not treated. By inhibiting several enzymes in the blood, lead can decrease hemoglobin, cause anemia, and impact overlapping systems. Lead impedes the conversion of vitamin D to its hormonal counterpart, thereby negatively affecting several important processes including cell

growth and maturation and bone and tooth development. The cardiovascular effect of lead exposure is a significant increase in blood pressure, which can adversely affect other organs. The effects of lead exposure on reproduction and development include decreased sperm count and quality, possible stillbirths and miscarriages, premature births and low birth weights, increased congenital abnormalities, and other birth defects. Although lead has not been proven to cause cancer, the National Toxicology Program has categorized lead as "reasonably anticipated" to be a carcinogen.

### REGULATIONS ON HUMAN EXPOSURE

The Lead Contamination Control Act of 1988 severely curtailed the release of environmental lead. The EPA has been regulating lead in water under the Safe Drinking Water Act for many years, establishing a 15 parts per billion (ppb) threshold for remedial action with a goal of zero lead in water. The EPA further requires that lead concentration in air in public spaces be no higher than 1.5 micrograms per cubic meter. If one pound (0.45 kg) of lead

**Graph of total emissions of lead separated by source versus time. Lead emissions reached their peak in 1972 but declined rapidly after it was restricted and banned to minimal levels by 1986, where it has remained ever since.**

arsenate or 10 pounds (4.5 kg) or more of metallic lead, lead acetate, lead chloride, lead fluoborate, lead fluoride, lead iodide, lead nitrate, lead phosphate, lead stearate, lead subacetate, lead sulfate, lead sulfide, lead thiocyanate, and tetraethyl lead is released to the environment, it must be reported to the National Response Center. The Occupational Safety and Health Administration (OSHA) limits lead in workplace air to 50 micrograms per cubic meter for an eight-hour-workday, 40-hour workweek. If the blood lead level of a worker reaches 50 micrograms per deciliter or higher, then the worker must be removed from the workroom. The National Institute of Occupational Safety and Health (NIOSH) set their designation of immediately dangerous to life and health (IDLH) to 100 micrograms per cubic meter for metallic lead and their recommended exposure limit (REL) to 0.050 microgram per cubic meter of metallic lead, lead oxides, and lead salts including organic salts such as lead soaps but excluding lead arsenate in workplace air for an eight-hour-workday, 40-hour workweek.

The good news about lead is that all of the efforts to reduce it in the environment seem to be working. Between 1987 and 1996 in the United States, lead emissions were reduced by 50 percent, and concentrations in ambient air decreased by 75 percent. In 1978, the number of children in the United States who had elevated blood lead levels numbered as much as 13.5 million. By 2002, the number had declined to about 310,000, and the decline has continued to the present. These impressive results are not only from legislative action but also mainly from a strong education and outreach campaign.

## London "Killer Fog" London, United Kingdom December 5–9, 1952 Air Pollution

Coal was a commonly used fuel in the 1950s in London, United Kingdom. It heated homes, cooked dinners, and fueled industrial furnaces and boilers, both in London and around the rest of Great Britain. Its connection to the frequent fogs as thick as "pea soup" was well known. In 1905, a London physician coined the term *smog* by combining the words *smoke* and *fog* to describe the way the high humidity in London combined with smoke from burning coal to form a particularly dense and long-lasting atmospheric pollutant. Today, the word *smog* has become synonymous with the haze or reduced visibility caused by many types of air pollution, not just that associated with burning coal. To be precise, recent usage requires the addition of a modifier that specifies the source of the smog. That described in 1905 is *London type*, or *classical*, smog and is formed by smoke or particulate as a primary air pollutant. In contrast, *Los Angeles*, or *photochemical*, smog is caused by atmospheric chemical reactions of petroleum hydrocarbons from automobile exhaust and sunlight and forms secondary air pollutants.

Midday smog in Piccadilly Circus, London, 1952 (Central Press/Hulton Archive/Getty Images)

Total suspended particulate (TSP), microscopic particles of dust with average diameters of less than 50 micrometers ( $\mu\text{m}$ ), was recognized early in the development of air pollution control laws as a significant threat to public health and the environment. If coal or any organic material is burned at a low temperature and without enough air, such as in a home stove or fireplace, it gives off smoke, a visible product of its incomplete combustion. Entrained in this smoke are a variety of hot gases and vapors as well as small carbonaceous particles that are carried up the chimney and are generally known as soot. The place that most typifies the need for control of particulate air pollution is the city of London, which has historically been filled with smoke and covered with soot.

If coarse TSP in the range of 10–50  $\mu\text{m}$  is deposited in the part of the respiratory system that is relatively self-cleaning including the nose, throat, and connecting airways that are lined with mucus, the short-term health impact is minimal. The particles are constantly flushed from these areas to the back of the throat, where they are swallowed and digested in the strong acids of the stomach. Usually within a few hours of exposure to TSP, the lungs and respiratory system have been cleared. For the normal healthy adult, short-term exposure to coarse particulate matter is a minor annoyance. It can lead to coughing, throat irritation, and a temporary reduction in lung function or, at worst, sinus infections.

If, however, children, elderly adults, or people who have existing heart or lung diseases, such as asthma; chronic obstructive pulmonary disease (COPD), including bronchitis or emphysema; congestive heart disease, in which heart muscles are too weak to pump blood efficiently; or ischemic heart disease with arteries blocked by cholesterol, are exposed to TSP, the self-cleaning mechanisms in their lungs are not strong enough to clear the particulate quickly. Individuals who have these and other types of medical conditions are not able to breathe normally and start to cough and are unable to catch their breath. Eventually, they may need to be admitted to hospital emergency rooms for treatment, and their risk of premature death from their preexisting heart or lung disease significantly increases.

In 1300, King Edward I banned, under penalty of death, the burning of coal because of the soot and odor it produced. This law was quickly rescinded as the forests around England's major cities began to disappear rapidly. For the next 600 years, England wrestled with ways to balance the need to run its economy, largely based on the burning of coal, and its need for clean air. London was especially suscep-

tible to the effects of burning coal. Only a few miles from the North Sea, the city's weather for much of the year was cold and damp. Particulate is able to stay suspended for long periods under these conditions and become very concentrated in the atmosphere by latching onto the water vapor present in this high-humidity environment.

### THE POLLUTION DISASTER

During the night of Friday, December 5, 1952, a layer of warm, moist air was trapped over the city by the beginnings of an unusually long-lasting temperature inversion. With little or no wind, particulate emitted by thousands of coal burning devices began to accumulate in the humid atmosphere. The fog thickened, and visibility dropped to a few feet. The stage was set for the great 1952 London Fog disaster, which was perhaps the worst air pollution disaster of all time. For the next 114 hours over five days, London was continuously shrouded in smog to the point where it became difficult for residents to tell night from day.

On Saturday, December 6, 1952, Londoners awoke to darkness. As they ventured outside, the pollution began to cause serious health problems, especially to the "at risk" population. The hospitals began to become overrun with patients. The ambulances stopped running as a result of the chaos and poor visibility, and thousands of gasping Londoners were forced to walk through the smog to the city's hospitals. In all, 500 people died in London that day of smog-related complications. Even animals suffered from the smog. Cattle in the city's Smithfield market fell over gasping and died, and their carcasses were simply thrown away before they could be slaughtered and sold.

By Sunday, December 7, visibility fell to one foot (30 cm). It was impossible to travel, because the roads were littered with abandoned cars. Midday concerts were cancelled because of the total darkness. Smog was infiltrating homes by then. Archivists at the British Museum noted smog in the book stacks. A theater had to be closed when fog inside the building forced patrons and performers to leave because they could not breathe. It was reported that in certain low-lying areas of London's East End, visibility was so poor that people could not see their own feet. This infiltration of smog into buildings began to cause adverse health effects for people who were not venturing outside. The steady stream of dying patients to hospitals continued. The lips of the dying were blue. Tobacco smoking and chronic exposure to pollution had already weakened the lungs of those most affected by the smog, triggering

massive inflammations. In essence, the dead, who numbered more than 750 this day, had suffocated.

Monday, December 8, and Tuesday, December 9, were no better. Road, rail, and air travel continued to be almost impossible. Conditions worsened and the death toll was estimated at 900 during each of those two days. Then late on December 9, the wind swept in unexpectedly, and the killer fog vanished as quickly as it had arrived, but the death of people affected by the smog continued for several weeks until just before Christmas. The mortality rate of bronchitis and pneumonia increased more than sevenfold as a result of the smog.

London is a big city, and many people die every day. Officials realized that there was a severe public health problem by the number of people swarming the hospitals, but it was not until the undertakers noticed that they were running out of coffins and the florists out of flowers that they realized the death rate had also increased. Only later was it determined that the number of deaths during the days of the smog was three or four times normal.

Health officials estimated that the smoke-laden fog was responsible for the premature death of about 4,000 people. A recent study estimated the longer-term death toll for the increased mortality rate through December 1952 at 12,000. For perspective, about 30,000 Londoners died in the Blitz during World War II. Most susceptible were those already suffering from chronic respiratory or cardiovascular illness, and they made up the majority of the deaths, but even some healthy people died. Some public health officials cautioned that the elevated death rate also could be blamed on an outbreak of influenza that occurred at about this same time.

During the disaster, average sulfur dioxide and TSP concentrations were estimated at 0.6 part per million (ppm) and 1,400 mcg/m<sup>3</sup>, respectively. The United States air quality standards limit sulfur dioxide levels to no greater than 0.03 ppm and TSP levels to less than 260 mcg/m<sup>3</sup>. Some estimates place the amount of pollution trapped in the inversion at 1,100 tons (1,000 metric tons) of smoke particles, 2,200 tons (2,000 metric tons) of carbon dioxide, 154 tons (140 metric tons) of hydrochloric acid, 15.4 tons (14 metric tons) of fluorine, and 407 tons (370 metric tons) of sulfur dioxide that were converted to 880 tons (800 metric tons) of sulfuric acid.

### THE AFTERMATH

Although this was not London's first "killer fog," as similar events had taken place in 1813, 1873, and 1891, the catastrophe in 1952 is widely regarded as spurring extensive epidemiological research into the

**Graph of smoke, atmospheric sulfur dioxide, and resultant deaths versus time during the London fog disaster in the early part of December 1952. The elevated death rate did not return to normal levels until January 1953.**

public health effects of air pollution. After an initial phase of skepticism, the British Parliament eventually became convinced by the mortality data and, in combination with strong constituent pressure, passed the 1956 Clean Air Act. This piece of legislation placed tighter controls on the release of air pollution and established stricter monitoring standards. In 1956, despite this new legislation, another killer fog struck the city, killing an estimated 1,000 people. Its causes were essentially the same, particulate and SO<sub>2</sub> trapped by a temperature inversion.

The 1956 Clean Air Act gave local governments the authority to provide funds to households to convert their coal-fired heaters for use of cleaner sources of energy such as gas, oil, smokeless coal, or electricity. Later, the 1968 Clean Air Act, which was aimed at industry and introduced the use of taller chimneys, was passed. Unfortunately, there was another smog incident in 1969.

Fortunately, today, in most developed countries, smog events such as the 1952 London Killer Fog are very rare. Changes in fuel types, more efficient furnaces, and the use of air pollution control devices have greatly reduced the amount of TSP released into the atmosphere. In the rapidly growing large and mid-size cities of India, China, and parts of Latin America, however, the potential still exists for a similar air pollution disaster. The use of coal, wood, diesel oil, and other forms of particulate-rich fuel combined with lax or unenforced air pollution control

regulations, in combination with just the right meteorological conditions, could result in a repeat of the 1952 London Killer Fog.

#### Los Angeles air quality legislation Los Angeles, California 1943–present Air Pollution

One of the first names given to the area that would become Los Angeles by the 16th-century Spanish explorers was La Bahía de los Fumos, or “bay of smoke.” It seemed the smoke from their campfires tended to accumulate in the warm, still air of this portside on the west coast of the New World. By 1777, drawn to the area by the harbor and nearby freshwater rivers, Spanish missionaries established a small village and named it El Pueblo de Nuestra Señora la Reina de los Angeles del Rio de Porciuncula, roughly translated to the village of Our Lady, queen of angels on the Porciuncula River. Unlike on the East Coast of the United States, population growth was slow in the small village of Los Angeles, as it became known, with an estimated population in 1820 of only about 700 full-time residents. The situation changed in 1848, when gold was discovered in the foothills of the Sierra Nevada, some 400 miles (643.7 km) to the north. By 1850, California had declared itself to be a state and the population of Los Angeles had more than doubled to 1,600.

By 1876, Los Angeles was connected to the rest of the United States by the completion of the Southern Pacific transcontinental rail line, and, in 1892, a second “black gold” rush took place, when oil

was found in the plains south and southwest of the Santa Monica Mountains, Puente Hills, and Santa Ana Mountains, which surround most of modern-day Los Angeles and outline the 1,600-square-mile (4,144-km<sup>2</sup>) Los Angeles basin. With the oil, people and industry arrived, and by 1923, with 25 percent of the world’s oil produced within and around the city, the population had grown to almost 600,000, as one-third of all the people in California lived in Los Angeles. An unforeseen environmental benefit resulted from the oil discoveries, in that oil and associated natural gas quickly replaced coal as Los Angeles’s fuel of choice. As a result, the city inadvertently avoided an early air pollution crisis that certainly would have developed from the use of coal.

As the population grew, however, urban sprawl pushed people to outlying areas, away from manufacturing and business centers. To accommodate these population shifts, Los Angeles developed one of the most extensive urban mass transit systems in the United States. At its peak in the early 1940s, the Pacific Electric Railway operated more than 2,800 scheduled streetcars, along with high-speed interurban trains on more than 1,100 miles (1,770 km) of track. Many factors contributed to the demise of the Los Angeles rail system, including the widespread availability of affordable, mass-produced automobiles; inexpensive gasoline; and opening of the freeway system. Interurban rail service ended in 1961, and streetcars stopped running in 1963. It was another 30 years before the city had another rail-based mass transit system.

As the population of California increased from 7 million in 1940, to 15 million in 1960, and 30 million in 1990, there was a concurrent increase in the use of automobiles, buses, and trucks; generation of electricity; increased refinery production; and burning of fossil fuels. As more pollutants were put into the air, the factors that made Los Angeles such an attractive place to live—a flat-lying plain, a steady warm temperature (average 65°F [18°C]), a dry climate, surrounded by high sheltering mountain ranges, with mild winters, moderated by the nearby Pacific Ocean—became the main reasons why the air was becoming unbreathable.

#### CONTAMINATION OF THE AIR

In addition to helping to moderate Los Angeles’s weather, the mountain ranges surrounding the city also tended to trap air pollutants by restricting horizontal airflow and encouraging the formation of marine layer temperature inversions. This happens when cooling ocean water lowers the temperature of the air near the surface. Warmer, overlying air acts

Smog accumulating in the Los Angeles Basin begins to cover the city. (Jose Gil, 2008; used under license from Shutterstock, Inc.)

as a lid and prevents the cooler air below it from mixing or dispersing. This cool air creeps in over the city from the west and stays there, trapping pollutants and causing early morning to midday fog. This occurs most commonly in early spring through late summer.

By 1943, city residents began to notice, on a regular basis, that the cool morning fog stung their eyes and lungs. In 1944, the Los Angeles Bureau of Air Pollution Control was formed to “investigate the origin and causes of all known sources of air pollution.” Outlying suburbs and communities downwind of Los Angeles also formed similar air pollution control bureaus, boards, and departments. These early efforts by this patchwork assembly of politically weak and uncoordinated agencies to reduce emissions from the worst offenders, including railroads, lumber mills, and oil refineries, through education and voluntary cooperation were ineffective and, in summer 1946, Los Angeles and its nearby suburbs and unincorporated areas suffered through the worst air quality season ever, with visibility in downtown areas often reported as less than one mile (1.6 km) and thousands of people complaining about burning eyes and noses. This public outcry mobilized elected officials throughout the area, and, in October 1947, the Los Angeles County Air Pollution Control District (APCD) was formed to absorb and unify all other city and county air pollution programs.

### LEGISLATION TO REDUCE AIR POLLUTION

Focusing its early efforts on major smoke producers, by 1951, APCD had forced significant reductions in smoke emissions from iron foundries and open-hearth steel mills. The APCD also successfully mandated floating roofs for large oil and gasoline storage tanks to reduce the evaporation of hydrocarbons into the atmosphere. Without the large

amounts of coal that was being burned in other American metropolitan areas, and because of rigorous enforcement of antismoke laws, Los Angeles became one of the first “smoke-free” cities and started to be recognized as a national leader in air pollution control. As the 1950s progressed, APCD began to make efforts to control sulfur dioxide ( $\text{SO}_2$ ) emissions. The agency forced oil refineries to reduce  $\text{SO}_2$  emissions, successfully ended the open burning of garbage in landfills and, despite widespread public opposition, banned the use of residential garbage incinerators. This action ultimately cost the APCD director his job and raised the city’s waste disposal costs by \$20 million. By the middle of the 1950s, with all known major stationary industrial or commercial sources of air pollution within the Los Angeles basin eliminated or regulated, air quality should have improved, but it did not. Consequently, attention began to shift to the automobile, the one remaining source of air pollution that most scientists and engineers had dismissed long ago as a significant cause of smog.

Dr. Arie Haagen-Smit, working at California Institute of Technology, cobbled together equipment and, using techniques developed in the fragrances industry, successfully created a simulated gaseous atmosphere that had the look, smell, and physical effects of Los Angeles smog. He did this by exposing automobile exhaust to ultraviolet light in the presence of nitrogen dioxide, which was present as a result of low-temperature combustion of oil or natural gas. The chemical reaction created ozone and peroxyacetyl nitrate, the causative factors in the adverse health effects of Los Angeles’s photochemical smog. Neither the citizens of Los Angeles, who loved their cars and were not eager to accept any responsibility for fouling the air they breathed, nor the oil companies that made or sold the gasoline, nor the automobile companies that manufactured the

cars and buses were eager to embrace this new finding. Both industry and the public at large vigorously resisted changes in engine design, fuel composition, or driving habits. In 1954, Los Angeles reported 2.4 million motor vehicles, the highest number on the road of any city in the world. These cars, trucks, and buses consumed almost 5 million gallons (18.9 million L) of fuel every day. A 1966 study by APCD found that of the 16,000 tons (14,515 metric tons) of air pollutants emitted every day within the Los Angeles basin, 80–90 percent was from automobiles.

Armed with irrefutable scientific evidence, APCD initiated a three-phase attack on the problem of automobile exhaust. It began to fund technological studies to help develop better ways to control or reduce exhaust gases; it started a public education campaign providing methods to reduce air pollution and fuel consumption from automobile usage; and it requested that automobile makers consider engine modifications to reduce emissions. Years passed with no major breakthroughs, and, consequently, Los Angeles County sought to involve California state government in the problem.

In 1960, the California Motor Vehicle Pollution Control Act was passed. This bill mandated the first set of air pollution control standards for tailpipe emission in the country. It set a limit of 275 parts per million (ppm) total hydrocarbons and 0.5 percent by volume of carbon monoxide. The statewide Motor Vehicle Pollution Control Board had to certify any pollution control device claiming to meet this standard, and the law, cleverly written, created an instant mass market for the first such device that could be developed. At that time, one in every 10 cars built in the United States was sold in California. By August 1960, 100 companies, competing for an estimated \$700-million market, were frantically working on anti-smog pollution devices. In 1964, four devices developed by private companies were certified including three types of catalytic converters and one flame afterburner. This meant that one of these devices had to be installed on every new car sold in California after June 1965. In response, all of the major American automobile manufacturers, Ford, General Motors, and Chrysler, announced that they had developed their own emission control techniques. These devices included earlier versions of more modern systems that are standard equipment on new cars today such as balanced fuel and air injection systems, exhaust gas recirculation devices, catalytic converters, and positive crankcase ventilation devices. None of the private company devices certified in 1964 ever went into use. Later, the Motor Vehicle Pollution Control Board became the current California Air Resources Board, or CARB, which

has much broader powers to regulate stationary and nonstationary sources of air pollution.

In 1963, the federal government took a more active role in regulating the quality of air in the United States. Urged by Presidents Kennedy and Johnson, Congress passed the new Clean Air Act, which remained focused on research and funding, but not enforcement. By 1965, in the face of mounting public pressure as well as increased scientific evidence linking automobile exhaust to serious air pollution conditions, an amended Clean Air Act was passed. This amendment established vehicle exhaust emission limits modeled after those in California. The new law required emission control devices on all 1968 model cars sold in the United States. By then, however, air pollution control officials in California realized that the standards passed in 1960 were not stringent enough to address the Los Angeles smog issue. They wanted to pass even tougher air pollution control mandates than the federal legislation, a decision bitterly opposed by the automobile industry. They legitimately feared the technological and cost challenges associated with trying to meet 50 different emission standards in 50 different states. The final compromise reached with the proposed bill (the Air Quality Act of 1967) allowed the federal government to set emission standards everywhere in the country except California, a legislative condition that remains in effect to this day.

Not satisfied, California continued to lead the nation in air pollution control efforts. Its 1968 Pure Air Act proposed a set of far-reaching concepts that included requirements for state car fleets to use hybrid; steam; and natural gas-powered vehicles. California was also a key player in a 1969 federal lawsuit against the major American automakers for “conspiring to prevent, obstruct or delay the introduction of devices to control vehicular emissions from 1953 onward.” Reminiscent of the government’s massive legal battle with the tobacco industry and using data and information obtained primarily from California’s struggle to impose vehicle emission standards, the suit progressed slowly through the courts, hampered by lack of support from the Nixon administration. Not satisfied with its progress, Los Angeles County filed its own lawsuit in federal district court for \$100 million to recover costs associated with administering its antismog program and medical expenses for residents whose health had been impacted by air pollution.

Realizing that the California suit was probably the first of numerous similar state filings, as both New York and Illinois were considering actions, the automakers agreed to a deal with federal prosecutors. Although admitting no guilt, they agreed no

longer to conspire to obstruct development of emission control systems and to make royalty-free patent licenses available to any company wishing to develop or install these types of devices. This federal settlement, approved in late October 1969, resulted in the dismissal of all current and future state suits. In April 1972, the U.S. Supreme Court refused to hear a challenge initiated by 18 states seeking to overturn the ruling. The federal courts blocked similar lawsuits from proceeding in 1973.

Despite their losses in the courts, Los Angeles and California succeeded in raising the control of automobile exhaust emission to the level of a national policy issue. They also established a tradition of experimenting with far-reaching air pollution control measures, including pressing the federal government to require the use of unleaded fuels. A strange dichotomy has been occurring during Los Angeles's long fight to clean its air: The city continued to expand its highway system, dismantle its public transportation infrastructure, and encourage urban sprawl on a scale that essentially requires everyone to have a car and to drive it long distances. Despite this contradiction, since 1990, overall concentrations of metals, volatile organic compounds, ozone, sulfur dioxide, and particulates have steadily declined within the Los Angeles basin. Although still far from ideal, air quality generally has improved, despite the steady increased growth in population and private vehicle use. Clearly, the early aggressive efforts in air pollution control by Los Angeles County and California have led to a sustainable dynamic between economic growth and air quality. Whether that dynamic will continue to be successful into the future will depend, in large part, on the ongoing leadership and farsightedness of agencies such as the APCD and CARB.

**Air Pollution** There are few products that have changed building construction practices around the world as significantly as oriented strand board (OSB). First gaining widespread use in the late 1970s, OSB is a stronger, cheaper, and more versatile building sheathing material or structural panel than plywood. Manufactured from the renewable resource of specially cultivated, fast-growing, small-diameter trees, OSB was produced by the United States and Canada in 2001 in a total combined amount of more than 20 billion square feet (1.86 billion m<sup>2</sup>), and today its production rate far surpasses that of plywood.

This engineered "board" or panel is actually a series of layered mats consisting of thin, specially oriented or arranged wooden flakes or wafers sawed or chipped from logs and then mixed in a heated, pressurized process vessel with wood fibers and a waterproof exterior grade epoxy binder. The finished product is extruded as a large mat of predetermined thickness and cut to a standard size, usually four feet (1.22 m) wide by eight feet (2.44 m) long. Finished panels are used for exterior sheathing on residential houses and commercial structures and in other construction applications.

The manufacturing of OSB results in the generation of a variety of air pollutants including sawdust particulate from wood processing and handling, volatile organic compounds (VOCs) from thermosetting phenol-formaldehyde and isocyanate-based resins, and hydrocarbon emissions from fuels used to fire dryers and other process equipment. Modern OSB plants in the United States have been designed to comply with current air pollution control requirements, and most generally are operated in an environmentally conscientious and careful manner. The vast majority of plants use wood residue from processing operations as most of their fuel, although oil or natural gas also is used as fuel supplements or backups. As the manufacturing of OSB began to expand in the late 1970s through the 1980s, however, not all companies were as diligent as they should have been in ensuring that their operations were consistent with Clean Air Act regulations.

#### BACKGROUND

The largest manufacturer of OSB in the world is the Louisiana-Pacific Corporation, or LPC. Established in 1972, LPC was formed when its predecessor company (Georgia Pacific, or G-P) was found to

be “monopolistic in nature” by the Federal Trade Commission, which ordered G-P to divest itself of timber assets in the southern United States. By the early 1980s, LPC had grown to more than 13,000 employees working in more than 100 manufacturing facilities across the country. Today, after restructuring in the late 1990s, LPC has some 6,500 employees and \$2.6 billion in annual sales. It is no longer in the wood pulp industry and currently focuses its operations on producing, in addition to OSB, hardboard and other structural-type building materials utilizing engineered or composite wood products.

LPC was quick to recognize the value of the OSB market and aggressively sought to become the leading supplier in the United States. To that end, and with the help and encouragement of the state of Colorado’s economic development authority, in 1983, LPC began preparations to build two large OSB plants in Colorado, one in Olathe, about 300 miles (482.8 km) southwest of Denver, and another in Kremmling, about 100 miles (160.9 km) northwest of Denver.

When a company plans to construct a new plant or announces an expansion or major renovation to an existing facility, especially if that expansion or renovation results in increased production capability, one of the first things it must do is obtain new air pollution discharge permits. The applications, called Permits to Construct, must be approved by either the federal or the state environmental regulatory agency (in Colorado, the Air Pollution Control District [APCD]) before any groundbreaking or site preparation takes place. This ensures an adequate opportunity for public comment and gives the regulatory agency the chance to make certain that appropriate air pollution control devices are included in plant design. LPC followed the appropriate procedures and applied to the Colorado APCD for the necessary permits.

The permits were issued shortly before construction began and allowed the discharge of up to 78 tons (70.8 metric tons) per year of carbon monoxide and 102 tons (92.5 metric tons) per year of VOCs at Kremmling. Similar permits were issued by APCD for the Olathe plant, limiting carbon monoxide to 112 tons (101.6 metric tons) per year and VOCs to 116 tons (105.2 metric tons) per year. Emission limits were to be enforced by restricting the amount of product each plant could produce. The APCD determined a ratio of the number of tons of manufactured OSB produced to the number of tons of air pollutants emitted. A limit on production, enforceable by spot audits of manufacturing records, customer invoices, and other documents, limits the amount of air pollutants.

## POLLUTION AT THE FACILITIES

The Clean Air Act, which at that time was being administered in Colorado by the U.S. Environmental Protection Agency (EPA), not the APCD, established minimal air quality standards for each region of the United States. Incorporated into these standards is a program whose objective is the prevention of significant deterioration (PSD) of air quality. The special regulations contained within the PSD program are intended to provide extra protection to those areas where the air is already relatively clean. The PSD program requires industries seeking to increase the amount of pollutants released to the atmosphere in “attainment areas” to obtain special permits that limit the amounts of pollutants that can be discharged. It also mandates the installation of very stringent and expensive “best available control technology,” or BACT, air pollution equipment. PSD rules apply to major stationary sources with the potential to emit 250 tons (226.8 metric tons) per year of any air pollutant. LPC overlooked, did not consider, or perhaps intentionally ignored that the Olathe and Kremmling OSB plants were in designated attainment areas and required special air permits from the EPA before they could be built.

## LEGAL ACTION AGAINST LPC

One day in September 1983, an EPA inspector driving to another facility noticed smoke billowing out of a stack at the LPC Kremmling plant. Information gathered during his visit to the plant that day and on subsequent inspections led him to advise facility operators at both Kremmling and Olathe that the OSB plants were major stationary sources and required PSD permits. LPC did not agree, and thus began five years of legal and technical battles, eventually leading to a civil enforcement action and a trial in federal district court.

The EPA was seeking severe financial penalties against LPC for violating important provisions of the Clean Air Act by not obtaining PSD permits prior to construction of the Olathe and Kremmling plants. The EPA also asked for a court order barring LPC from any further Clean Air Act violations. As the defendant, LPC contended that it had obtained valid air permits from the APCD and that the control technologies already in use at both plants based on APCD requirements are the same ones that would have been required under a PSD permit. In addition, the plant had not violated any air quality standards, and, by the time the case had reached trial, LPC had already applied for PSD permits from the EPA.

In its 1988 decision, the court essentially agreed with LPC. The evidence and testimony presented

did not indicate that the company had gained any economic advantage or benefit by not applying for and obtaining the PSD permits prior to construction; nor was public health apparently impacted or threatened by plant operations prior to issuance of the permits. The presiding judge, however, was hesitant to let LPC escape without any penalty because, ultimately, it was LPC's responsibility to apply for and obtain all permits legally necessary to run its business. He assessed a modest \$65,000 fine against the company.

### OTHER VIOLATIONS

Although it is tempting to sympathize with LPC as the victim of overzealous and unreasonable government regulation, major issues related to the company's air emissions at Olathe and Kremmling started to surface during and shortly after the EPA's civil enforcement case.

In 1984, one of LPC's unions notified the APCD that the company had not included information on formaldehyde emissions from its press process lines. This required LPC to apply for new permits to cover these emissions, and these new permits reduced production to a maximum of 160 tons (145.2 metric tons) per day for both plants. In June 1985, APCD threatened to revoke LPC's air permits at both plants because of violations of smoke discharge limits. Because of the threatened revocations, LPC installed additional air pollution control equipment at both plants and APCD issued yet another set of permits.

Another permit revocation was threatened by APCD in early 1986, and LPC again made significant improvements to the Olathe and Kremmling air pollution control systems, which included further restrictions on OSB production of no more than 50,000 tons (45,454 metric tons) per year or about 140 tons (127 metric tons) per day at each facility. LPC promptly exceeded these production limits at both plants in 1986, manufacturing 105 million tons (92.3 million metric tons) at each plant and, in 1987, producing 124 million tons (112.5 million metric tons) at Olathe and 94 million tons (85.3 million metric tons) at Kremmling. Once these production quantities were reported, LPC prepared yet another set of permit applications and forwarded them to APCD, requesting permission to increase production limits at both plants to about 78,000 tons (70,760 metric tons) per year.

In that same year, four families living within one quarter-mile (0.4 km) of the Olathe plant fled their homes and filed suit against LPC for creating such noxious air pollution that they could no longer live

in the area. Witnesses testified during the trial that the plant increased production rates and associated air emissions at night, when state inspectors were less likely to be on duty and emissions were more difficult to see. The trial ended in 1993 with an award of \$2.3 million to the four families, with \$1.9 million of that amount included as punitive damages.

By 1990, LPC was back under the scrutiny of the EPA, with the agency's air pollution scientists investigating discrepancies between the amounts of air pollutants reported as emitted from the Kremmling plant and the amounts estimated from production volumes. The answer was simple: The facility was underreporting. On the basis of an investigation that started in Colorado, the EPA began to look at LPC facilities around the country. The company subsequently was charged with tampering with or disabling air pollution monitoring devices, filing false or inaccurate emission reports, and deliberately misleading federal air quality inspectors. In 1998, LPC pleaded guilty to these and other criminal violations and was fined \$37 million and sentenced to five years' probation. This was, at that time, the largest fine in Clean Air Act history.

The federal grand jury also charged the Olathe plant's superintendent and mill manager personally with Clean Air Act violations. Both individuals pleaded guilty, and the superintendent stated that the falsified pollution reports were prepared because of pressure from senior LPC managers to increase production volumes. The Kremmling plant closed in early 1992.

This conviction followed on the heels of a 1993 \$11-million settlement with USEPA for air pollution violations at numerous other LPC plants. As part of that settlement, LPC was required to install \$70 million worth of control equipment at various processing and manufacturing facilities in the northwestern and southern United States.

This was a turbulent time in the history of LPC, and the environmental problems the company was dealing with were symptomatic of a larger leadership gap and related dysfunctional business management culture. Eventually, the LPC chairman was replaced, and a new spirit of compliance and cooperation with environmental regulations and regulators took hold. Although LPC still struggles at times to fulfill its environmental commitments, the company's current success is not based on fouling the air of its neighbors or the communities in which it does business.

**Love Canal Niagara Falls, New York 1978**  
**Water Pollution** In the southeastern corner of Niagara Falls, New York (population 56,000), is a 36-square-block working-class neighborhood of neat, well-kept row homes, formerly part of a larger community known as Love Canal. Water plays a key role in defining the Love Canal as a neighborhood. Its northern and southern boundaries are demarcated, respectively, by Bergholtz Creek and the Niagara River, and the "center" of the neighborhood is now known as 99th Street, but it was at one time a dream turned nightmare.

In the early 1890s, William T. Love, an enthusiastic and visionary industrialist, moved to Niagara Falls to build a canal connecting Lake Ontario and Lake Erie. He was convinced that not only would the canal provide a convenient shipping channel bypassing the rough waters of the Niagara River to serve the region's growing industrial base, but the flow of water through it could be harnessed to provide hydroelectric power. Love's vision was that the canal would be the center of a large industrial complex and city of more than 200,000 people, with electricity generated by the rushing water that dropped some 300 feet (91.4 m) between lake elevations.

The project was never completed, because of the economic panic of 1893 and the development of alternating current, which allowed electricity to be economically transmitted over long distances. The development company formed by Mr. Love went bankrupt, leaving a large hole in the ground 3,000

feet (914.4 m) long, 60 feet (18.3 m) wide, and 40 feet (12.2 m) deep. Love Canal, as the excavation became known, encompassed an area of about 16 acres (6.4 ha), eight miles (13 km) north of Niagara Falls.

### POLLUTION OF THE CANAL

The canal served as a local swimming hole for neighborhood children until the late 1930s, when it was purchased at auction by the Niagara Power and Development Corporation. This was during the Great Depression, and it was decided that the best use for the land was to restore it to productive use. To do so, it first had to be filled in to a usable level. The city of Niagara Falls and several other nearby communities began using the undeveloped area as the municipal dump. Not only was typical household refuse placed there, but Niagara Falls also allowed

Teenager relaxing in Niagara Falls on the fence surrounding Love Canal, Upstate New York, ca. 1978 (© Bettmann/CORBIS)

chemical wastes from its very active petrochemical industry to be dumped into the canal.

In 1942, a local manufacturer of industrial chemicals, fertilizers, and plastics started using the canal as a dump site. In 1946, Hooker Chemical, now Occidental Petroleum, purchased the property as a solution for its waste disposal needs. Between 1947 and 1952, Hooker Chemical dumped 43 million pounds (19,505 million kg) of industrial chemicals into the canal. Hooker also allowed the U.S. Army and several of its contractors to dispose of material from chemical warfare experiments. By 1952, the canal had been filled to capacity. After ending disposal activities, Hooker placed a state-of-the-art hard-packed, dense, clay/ceramic cover over the filled area to isolate the waste material and prevent infiltration by precipitation.

About 250 different chemicals were buried, mostly pesticides, but also other organic chemicals such as hexachloro-cyclohexane (HCH), chlorobenzenes, chlorinated hydrocarbons, benzene, chloroform, trichloroethylene (TCE), methylene chloride, benzene hexachloride, phosphorus, and polychlorinated biphenyls (PCBs). Most troubling were reports that approximately 130 pounds (59 kg) of toxic dioxin was buried in Love Canal. This 16-acre (6.4-ha) parcel, which was converted in the early 1950s into baseball and football fields, had become one of the largest repositories of hazardous wastes in the world.

### **PUBLIC EXPOSURE TO POLLUTION**

In the post-World War II years, the population of Niagara Falls, like that of the rest of the country, was growing quickly, and land for new schools and housing was desperately needed. The city approached Hooker and offered to buy the property it had used as a chemical waste dump to build a school on it. Hooker initially refused, but under threat of condemnation through eminent domain, sold the property to Niagara Falls for one dollar, the minimal amount for a contract to be legally binding. In the 1953 purchase agreement, Hooker disclosed what they had used the property for, warned about the potential dangers of developing the site, and absolved itself of any liability associated with future use of the property.

Within a few months of the sale, construction of the 99th Street School began. However, building plans had to be redrawn quickly when a contractor preparing the site found several pits filled with chemicals. The new location placed the school directly on top of the chemical landfill, and in order to dig the

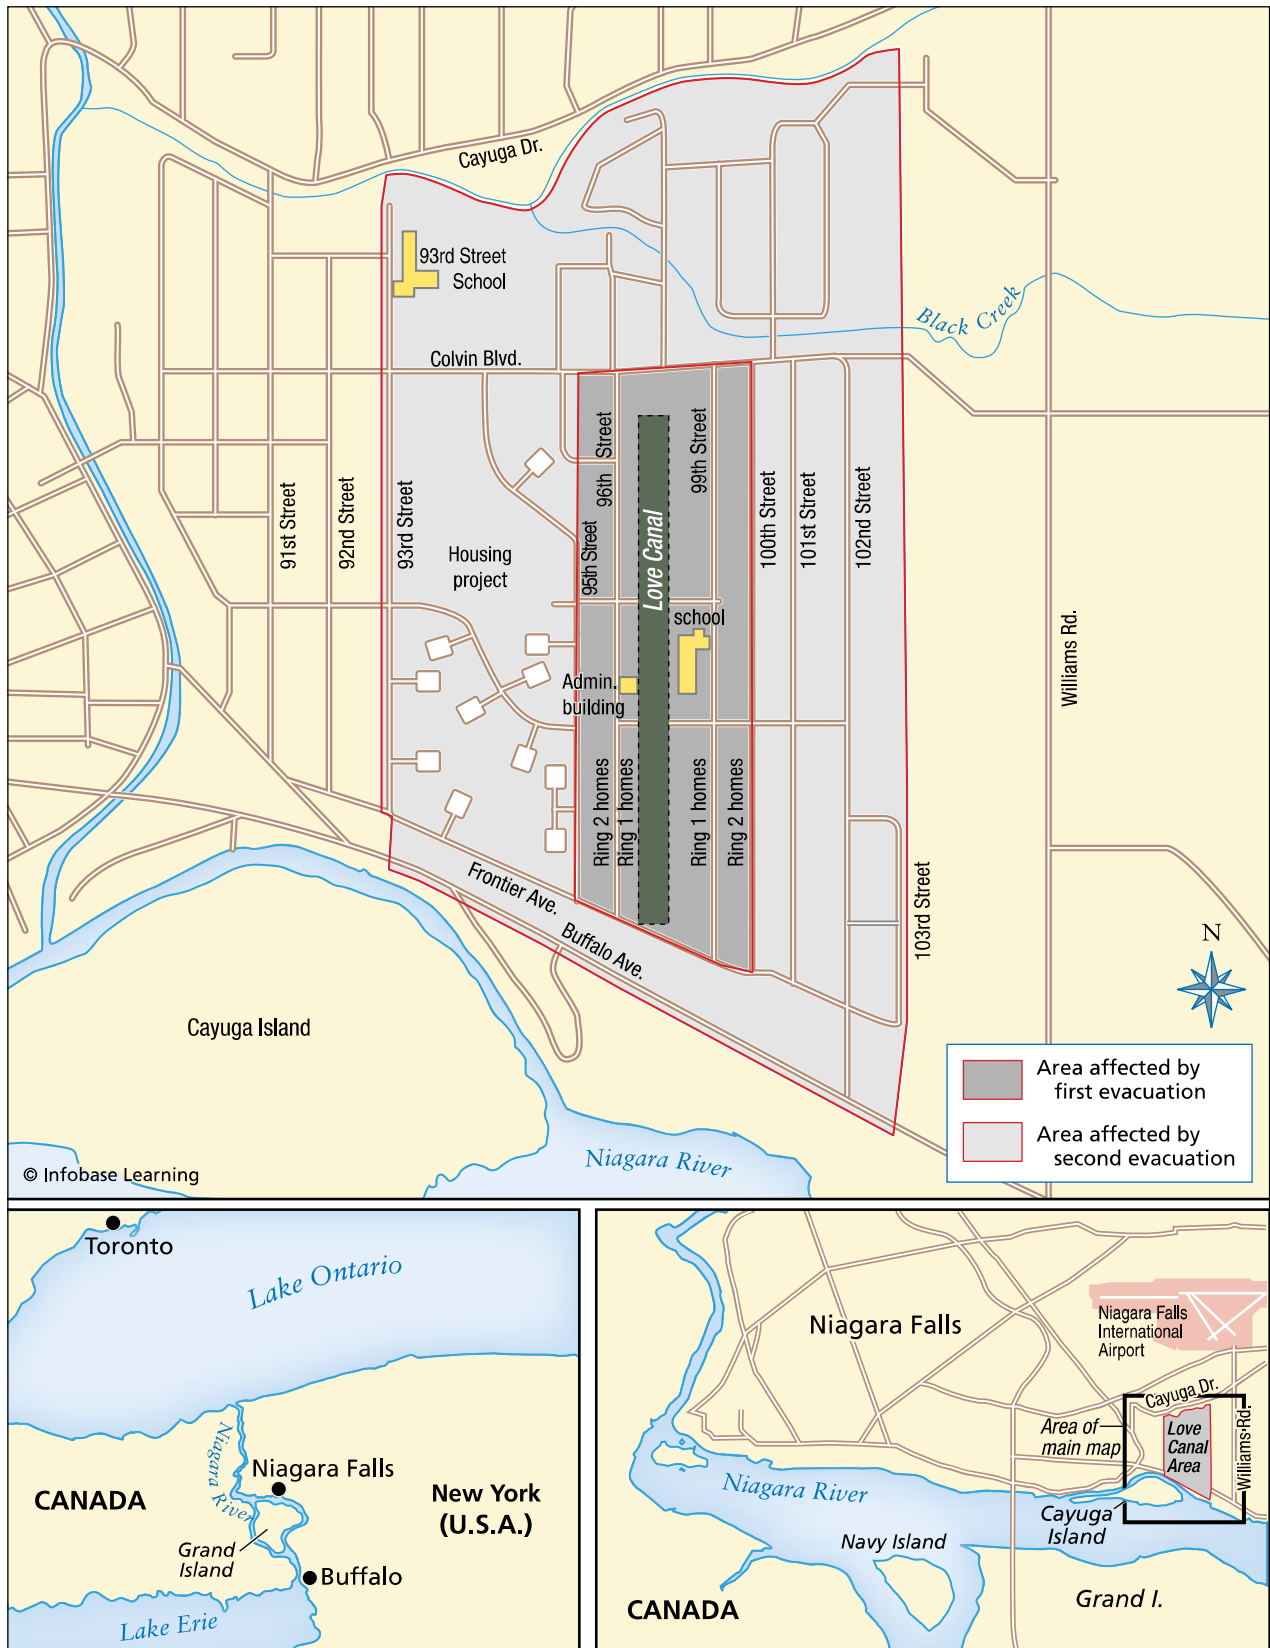

foundations, the tough clay cap Hooker installed to keep the waste isolated had to be removed.

By 1957, the Love Canal section of Niagara Falls was a neighborhood of about 200 houses, a large park, a winding creek, and a new 500-student elementary school. The city constructed sewers and installed water lines, further breaching the clay cover, for a mixture of low-income and single-family residences that were built on land abutting the disposal site. No disclosures were made to the families purchasing these homes about the potential risks associated with living so close to the chemical waste dump or even that the dump was there.

The geology of the Love Canal site played a major role in site development. Under a thin layer of topsoil ranging in thickness from a few inches to several feet is a layer of glacial till. This till is a mix of silt, sand, and gravel in a matrix of dense clay. Hooker recognized that one of the useful properties of this clay was that water did not move through it very quickly, if at all. The clay was relatively impermeable, making it ideal for waste disposal. Liquid chemicals and leachate from trash and other debris could be placed inside the hollowed-out partially completed canal, covered over, and would tend to remain in place. Although there were some natural variations in the till, sand lenses, and other higher-permeability zones, as long as water was prevented from having contact with and mobilizing the wastes, they would not present a significant migration pathway out of the disposal site. Underneath the till is sedimentary bedrock that is also fairly impermeable, further restricting migration. Love Canal was an appropriate waste disposal site, an impervious clay vault covered by a tight-fitting clay and ceramic lid.

As the lid or cover of the canal was breached, first by the school and later by sewer, gas, water, and other utility lines, water began to infiltrate the waste. Beginning in the 1960s, residents began noticing and complaining about strange odors in the area and about unusual substances that bubbled up in their yards and seeped through basement walls. The Love Canal vault was starting to fill with rainwater.

City officials investigated and attributed the odors to nearby chemical and industrial plants, but the problems only grew worse. Dogs and cats began to develop skin lesions. Children, after spending time in the school's ball field, started to have symptoms of skin irritation similar to poison ivy. Finally, in 1978, the "toxic time bomb" that Hooker had constructed and whose fuse was lit by the city of Niagara Falls, exploded. That year's record amounts of rainfall had filled the vault to capacity, and it began to overflow. Exploiting ancient drainage channels in the clay

(swales) that had been filled with more permeable sand and gravel, liquid wastes and contaminated groundwater began moving into the Love Canal neighborhood. On August 1, 1978, the *New York Times* front page story was about the chemical-laden leachate that had begun to drain onto the surface of the former dump site, entering streams, sump pumps, and low-lying areas throughout the residential community and onto the grounds of the 99th Street School.

Rotting drums containing pesticides “floated” to the surface in backyards and playgrounds, buoyed by a combination of frost heave and rising water table elevations. A swimming pool had been forced off its foundation from the hydrostatic pressure of the rising groundwater and was found to be floating on a layer of chemical waste. Foul-smelling puddles of unknown toxic substances appeared in ditches and other low-lying areas including the basements of some homes and on school grounds. Everywhere the air had the sickly sweet smell of solvents, and a number of children were treated for chemical burns on their hands and faces after playing outdoors.

### LEGISLATIVE REACTION

The city of Niagara Falls and state of New York were slow to react to the crisis. Since 1975, the Love Canal Homeowners Association had led an effort to investigate community concerns about the health of residents. They documented the high rates of cancer and birth defects occurring in the neighborhood. These efforts were aggressively opposed by both Occidental Petroleum, the successor company to Hooker Chemical, and many of their own elected officials, who still believed the chemicals were safely buried. It was not until a newspaper reporter from the local paper, *Niagara Gazette*, took samples from a sump pump in the affected area and demonstrated that the sludge contained the same chemicals Hooker had disposed of that governmental action began. Neither the school board, the city, nor Occidental Petroleum was willing to accept responsibility for the cleanup.

Faced with intense and growing media and public pressure, President Jimmy Carter declared a federal emergency at Love Canal on August 7, 1978, and approved emergency financial aid for the area. This was the first emergency funding ever authorized for anything other than a natural disaster. The U.S. Senate also issued a “sense of Congress” statement recommending that federal aid be allocated to address the serious environmental damage that had occurred. That same day, the New York gov-

ernor, Hugh Carey, told residents the state of New York would purchase the 200 homes most affected by the chemicals. By month’s end, 98 families had been evacuated, and 46 others had found temporary housing. Shortly thereafter, 221 families from the most contaminated areas left. The 99th Street School was closed and was eventually demolished.

Governmental officials again underestimated the extent of the problem. Neighbors of those whose homes had been purchased, some next door or across the street, were still concerned about their health and the health of their families. Property values had plummeted, and “buy one; get one” home sales were offered, with no takers. In May 1980, the U.S. Environmental Protection Agency (EPA) published the results of blood tests confirming that because of exposure to the toxic chemicals, Love Canal residents had suffered chromosome damage, greatly increasing their risk of developing cancer and having reproductive problems. Enraged by the findings and the government’s lack of action, residents forcibly held EPA officials hostage at a public meeting for two hours.

Confronted with escalating civil disobedience by respectable working-class people in conservative Upstate New York, President Carter agreed to evacuate all Love Canal families temporarily, pending appropriation of relocation funds. Eventually, almost 900 families were moved and their homes purchased.

### THE CLEANUP

The cleanup program was massive and incredibly expensive. None of the waste was removed: Safety analysis quickly demonstrated that the risks to workers and nearby residents from the excavation, packaging, and shipping of the mixed toxic waste were too great. Rather, a clay and synthetic cap was installed over the original 16-acre (6.4-ha) dump as well as another 40-acre (16-ha) contaminated area. A barrier drainage and leachate collection system was installed around the perimeter of the site to collect liquids that might leak out of the now-recapped fill area. Approximately 3 million gallons (11.4 million L) of contaminated groundwater and runoff is captured and treated every year before being discharged to the city’s sanitary sewer system.

Sewer and creek sediments that soaked up chemicals released from the dump were excavated and treated before being shipped to long-term disposal sites. The site is checked continuously for migration of hazardous chemicals through a system of groundwater monitoring wells. Current plans are to

maintain the cap, leachate collection and treatment systems, and monitoring program in perpetuity.

Occidental Petroleum settled some 1,300 homeowner lawsuits for \$20 million. Individual awards ranged from \$200,000 to \$1.4 million, depending upon how badly the family was affected. Occidental also reimbursed EPA for \$230 million in costs related to relocation of residents and remedial activities. The company also has assumed responsibility for the long-term operation and maintenance of the treatment system. The U.S. Department of Defense settled out for \$8 million, paid directly to EPA. The remainder of the cost, about \$160 million, was borne by the federal government and the state of New York.

### THE AFTERMATH

Residential areas southwest of the canal were demolished and are now separated from the rest of the city, along with the 70-acre (28-ha) recapped area, by an eight-foot- (2.5-m-) high, barbed-wire-topped, chain-link fence. It is unlikely anyone will ever live on the other side of that fence again. Parts of the community, however, have made something of a comeback. More than 260 homes previously evacuated west and north of the canal have been repaired and sold to new owners. Ten new apartment buildings have been constructed. Though access to the recapped area is still restricted, recreational buildings and facilities have appeared abutting the fence separating contaminated from clean. Finally, there are no more street signs pointing the way to Love Canal, and it cannot be found on maps; the area has been renamed Black Creek Village in a gesture to try to shake off the images associated with the actions of almost 30 years ago.

The events at Love Canal were directly responsible for the passage of CERCLA—the Comprehen-

sive Environmental Response, Compensation, and Liability Act, more commonly known as Superfund. This program, funded by a now expired tax on oil and chemical companies, provided the government the means to respond quickly and effectively to hazardous waste emergencies. It also held the polluter strictly liable for the environmental damage its wastes caused and allowed individuals to sue for personal and property damage resulting from improper disposal or spills of hazardous materials.

# M

**Magic Marker Site Trenton, New Jersey (1995–2001) Soil Pollution** In 1941, the Philco Company (later Ford Philco) purchased a 7.5-acre (3-ha) parcel of land in the heart of Trenton, New Jersey, one of the major industrial and manufacturing centers of the northeastern United States. Philco produced batteries for the military and needed a site with a skilled workforce that was close to the major transportation hubs of Philadelphia and New York. Trenton was the perfect location. At the time, the city of almost 125,000 was one of the country's leading manufacturers of steel, rubber, wire, rope, linoleum, and ceramics. The city's slogan, boldly emblazoned in huge letters across a bridge spanning the Delaware River and connecting New Jersey to Pennsylvania, stated, "Trenton Makes and the World Takes."

## BACKGROUND

Shortly after the end of World War II, the Gould Battery Company, a subsidiary of National Battery Company, purchased the property and began its own battery manufacturing operations. Gould manufactured two types of industrial and commercial batteries, starting batteries and deep-cycle batteries. Starting batteries are those that deliver a short, intense burst of electrical power needed to start engines, such as in automobiles and trucks. Deep-cycle batteries are designed to produce lower, steadier currents for electrically operated devices such as trolling motors on boats.

Both types of batteries are classified as lead-acid. Developed in the 1860s by a French physicist, lead-acid batteries are rechargeable and have a relatively high power-to-weight ratio; they deliver more elec-

tricity per unit weight than many other types of batteries made of different materials. This feature and their relatively low cost make lead-acid batteries ideal for use in cars, trucks, and even industrial equipment such as forklifts. The essential process of making a lead-acid battery has not changed much since the 1860s. A case (now plastic) is filled with a dilute solution of sulfuric acid and water. A series of specially perforated lead plates is placed inside this case. A mixture of lead oxide and powdered sulfates coats the plates, giving each plate either a positive or a negative charge.

The plates are arranged into groups (cells), with the positive and negative plates in each cell connected to positive and negative terminals on the outside of the plastic case. A typical car battery has six cells, which produce two volts per cell, for a total of 12 volts. An electrical current is generated by the chemical reaction that takes place between the positive and negative plates and is facilitated by the electrolytic (acid) solution. Electricity is produced if a complete circuit is formed between the positive and negative terminals, such as when a car's starter motor is engaged. Nearly 80 percent of the lead mined in the United States is consumed in the manufacture of lead-acid batteries. These batteries also have a very high recycling rate, primarily because of the credit given when a new battery is purchased and the old battery returned.

## POLLUTION OF THE SITE

As part of its manufacturer process, Gould decided to produce its own lead plates. This required the lead ore to be smelted to extract, or separate, the lead from other undesirable minerals or elements

present. Unless done under very controlled conditions, smelting, and particularly lead smelting, is notoriously damaging to the environment, producing large quantities of debris containing lead and heavy metals.

Gould also stored the sulfuric acid used to make the electrolytic solution in underground tanks on its Trenton site. Production operations gradually became more sophisticated until Gould was operating one of the most advanced commercial battery manufacturing plants on the East Coast. As process operations continued, however, the main building slowly started to decay, constantly under attack from the heat of the smelting operation and concentrated sulfuric acid being used to fill the finished batteries. Eventually, as Trenton began to lose its industrial base to other regions of the United States and foreign competitors along with many other northeastern manufacturing cities, Gould shut down its operations and donated the property to the county redevelopment agency.

After it had lain dormant for several years, in 1981, a Doral Industries subsidiary, Magic Marker Industries, purchased the site from the county agency. Doral refurbished the building and began production of pens, liquid crayons, and felt tip markers using such chemicals as propanol, butanol, and methanol. At peak production, Magic Marker had 200 employees. By 1989, Doral was in financial trouble, and its Magic Marker subsidiary filed for bankruptcy and abandoned the property.

During its operation, both as a battery manufacturer and as a writing implements company, neighbors complained about the often-overpowering chemical odors released by the plant. Given the dense population around the facility, which was directly across from an elementary school, local area residents became concerned that the abandoned building would become an eyesore and nuisance, attracting crime and posing a danger to children who might want to explore the building and grounds.

### THE INITIAL CLEANUP

It took several years, but by mid-1997, the Magic Marker Site, as the property came to be known, attracted the attention of the New Jersey Department of Environmental Protection (NJDEP). After several inspections, the NJDEP realized that they needed both financial and technical assistance to investigate the potential environmental impacts at the site. Acting at their request, the U.S. Environmental Protection Agency (EPA) identified some 200 drums and containers filled with acids, industrial solvents, and a wide variety of other chemicals. By

November 1997, the EPA and NJDEP initiated a joint \$450,000 removal program, financed largely under Superfund, that resulted in the safe sampling, repackaging, and off-site disposal of the abandoned chemicals. Part of this removal action included better fencing for the seven-plus-acre (2.8-ha) property, as well as sampling of adjoining sites to make sure contamination did not extend into the surrounding neighborhoods.

Once the immediate threat of a chemical catastrophe was abated, the question arose as to how to restore the property to productive use. Although the materials in containers had been disposed of properly, the upper 18 inches (45.7 cm) of soil across most of the Magic Marker Site was heavily contaminated with lead. In places, lead concentrations exceeded 1,000 parts per million (ppm). The NJDEP has established a safe level of lead in soil for residential uses of 400 ppm. With no one willing to buy and redevelop the site because of the widespread soil contamination, and with the risk to the public health and environment not serious enough to warrant the expenditure of additional Superfund monies, it seemed that the Magic Marker Site was destined to remain an abandoned, underutilized industrial facility for many years.

### BROWNFIELD CLEANUP

Brownfields are designated sites where historic industrial activity has resulted in a remedial or cleanup liability far in excess of the value of the property. These sites usually contain extensive or pervasive soil or groundwater contamination. Brownfields are most commonly associated with older urban areas where former industrial complexes once thrived that now lie fallow. Brownfield sites represent a blight on the community, a drain on the tax rolls, and a threat to the overall quality of life of nearby residents, who often are poor members of minority groups.

As the number of brownfield sites began to grow across the country, the EPA, New Jersey, and many other states responded with special brownfield development programs. These programs are designed to provide incentives for commercial builders to buy and redevelop the site, converting it into a benefit to the community. Incentives include protection from future liability or claims for damages as a result of the preexisting contamination, reductions in property taxes or awarding of tax credits, and, in some cases, federal or state grants that can be used to fund site remediation. In 2009, the EPA awarded more than \$160 million to communities in 44 states, two territories, and three tribal nations for use in property revitalization efforts.

To allow for redevelopment of the Magic Marker Site, in 1995, the EPA awarded a \$200,000 brown-field grant to the city of Trenton. The money was to be used for the demolition of the 175,000-square-foot (16,258-m<sup>2</sup>) manufacturing building and for field testing of an innovative remedial technology called phytoextraction. Phytoextraction uses the natural metal-absorbing capacity of plant roots, particularly of a certain type of Indian mustard plant (*Brassica juncea*), to remove physically or extract metallic contaminants that may be present within the root zone of the soil, generally the upper three feet (0.9 m). Working in cooperation with a private biotechnology company seeking to develop phytoextraction technology for commercial purposes, the city of Trenton began the cleanup program. The low cost and ease of application, as well as the nice look of the plant itself, made this remedial solution especially applicable for abandoned industrial sites in mixed-use or residential neighborhoods.

The soil at the Magic Marker Site is a mix of gravelly sand and industrial fill, including pieces of brick, slag, and cement. Two crops of the mustard plant and one crop of sunflowers were cultivated between 1997 and 1998. After harvesting, plant tissue samples were taken and assayed, or tested, for the amount of lead taken up by the plant. Soil samples also were collected as an additional check on the effectiveness of the phytoextraction process. To help make the lead more bioavailable, ethylenediaminetetraacetic acid (EDTA) and several other supplements were mixed into the soil before planting. Sampling results demonstrated that lead concentrations in the soil had been reduced by almost 60 percent in some parts of the study area. Mustard plant tissue samples contained up to 2,300 ppm lead, and sunflower stalks, roots, and leaves held up to 400 ppm.

Excavation and disposal of lead-impacted soil at the Magic Marker Site required the removal of 20,000 tons (18,144 metric tons) of material to ensure lead values met the 400-ppm residential cleanup criterion. The initial phytoextraction program produced only 500 tons (456 metric tons) of plant residues. It took an additional six to eight growing seasons, or about three years, before the lead contamination was reduced from an average of 1,000 ppm to the residential cleanup goal of 400 ppm. Other plants, such as corn and pumpkins, as well as the use of different soil amendments, are being evaluated to speed the removal of lead from the surface soils further. Eventually, the site will be used for a combination of public open space and residential development.

About 100 of these types of unused commercial and industrial sites are within Trenton, which lost

more than half of its manufacturing base between 1950 and 1990, as have many other cities throughout the United States. Similar sites in Trenton include a former brewery, auto salvage yard, and pottery manufacturer. The brownfields program at the federal level underwent a major expansion in 2006, when a change in the tax laws allowed environmental cleanup costs to be deducted in the year incurred, rather than capitalized over time. In addition, new legislation expanded the brownfields incentives to include deduction of expenses for the cleanup of petroleum products such as crude oil, crude oil condensates, and natural gasoline, which previously had been ineligible. Brownfield redevelopment programs, at both the federal and state levels, have played a major role in helping reclaim some of the most environmentally damaged property in and around the urban landscape.

**marine litter** The vast majority of ocean pollution does not occur as a result of the spectacular releases of oil from foundering tankers or oil well

blowouts, but as the quiet emptying of septic holding tanks from cruise ships at sea, the simple act of throwing bags of trash over the stern, and other seemingly innocent actions. This type of disposal, illegal under U.S. and most international maritime codes, is called marine litter and can be defined as any persistent discarded, human-produced solid material entering waterways, either directly by dumping or indirectly by being washed out to sea from rivers, streams, storm drains, and the like. Once discarded and in the ocean, most marine litter is very resistant to natural degradation, as shown in the following table.

Thousands of tons of marine litter are discarded into the ocean every year. This type of debris is a major problem along the world's shorelines and in coastal waters, estuaries, and oceans. Washed up on shore, marine litter poses both an aesthetic problem, detracting from enjoyment of the beach, as well as

a serious public health and ecological threat. It can kill or seriously injure many types of marine life and leads to disruptions in local ecosystems.

Approximately 25 percent of marine mammals, 15 percent of seabirds, and most of the world's oceangoing turtles have been affected to some extent by marine litter. One major problem is that of "ghost fishing" in which marine wildlife becomes entangled in discarded or lost fishnets. Other examples include plastic rings or bags that may ensnare marine life or fishing hooks and other debris that can be ingested by marine organisms.

Marine litter is found in all ocean and coastal settings including salt marshes, estuaries, and beaches. Isolation is no protection, as marine litter has been detected on the shores of Antarctica and floating in the Bering Sea. Its main component is plastic, which makes up about 60–80 percent of total marine

## Regulation of Ocean Pollution

People traveling in ships have routinely emptied sewage, trash, cooking water, oil, and other wastes into the ocean without regard to environmental impact. By the end of the 19th century, with its waterways and coastlines being heavily used, the United States began to recognize the need for control over this refuse. In 1899, the U.S. Congress passed the Refuse Act, which prohibited "throwing, discharging or depositing any refuse matter of any kind into the waters of the United States." The act was intended to reduce potential hazards to navigation, not to protect the environment. This was to be accomplished by reducing the amount of discarded floating wooden

crates and poles and sinkable metal and stone ballast debris. It focused on stopping the filling of channels by large amounts of trash, which required expensive dredging projects to keep the shipping lanes open. It was not until the early 1950s that a more unified and environmentally focused set of oceanic pollution-prevention regulations would be enacted.

In 1954, the United Kingdom organized a conference on pollution of the oceans by oil discharged from ships. This conference produced the International Convention for the Prevention of Pollution of the Sea by Oil. This was the first multinational treaty focused on protecting the environment. In it, the signatory

### MARPOL 73/78 DESCRIPTION OF ANNEXES

Annex	Topic	Effective Date
I	Oil	October 2, 1983
II	Noxious liquids carried in bulk	April 6, 1987
III	Harmful substances carried in packaged form	July 1, 1992
IV	Sewage from ships	United States not included
V	Garbage (trash) from ships	December 31, 1988
VI	Air emissions	Not yet in force

a. Annexes I and II are mandatory on all treaty signatories.

b. Annexes III, IV, and V are optional and not binding, unless the signatory country has specifically accepted them

debris. In more developed shorelines of heavily used waterways, such as the shipping lanes of the Atlantic Ocean, however, plastic waste can be as much as 90–95 percent of the total litter present.

Land-based sources are responsible for almost 80 percent of the volume of marine litter present in the oceans and in near-ocean habitats. This debris is transported by urban runoff through storm drains, from industrial and municipal discharges of untreated or only partially treated wastewater, and from the intentional or inadvertent disposal of trash into or near waterways. The second source of marine debris is that from oceangoing vessels such as commercial and recreational boaters, fishing crews, and offshore oil and gas exploration and production facilities. Solid wastes from these sources include wood, food wastes, glass, plastics, paper, cans, and cardboard. A typical cruise ship, for example, gener-

ates about eight tons (7.2 metric tons) of trash during each week of a voyage. Usually, this trash is burned, or incinerated, while the vessel is at sea, with the ash and residues unloaded at port or flushed into the ocean as sinkable waste. Sinkable wastes are those that have been processed in some way such as shredding or incineration so that they quickly fall to the ocean floor, thereby posing a less immediate risk to sea life and navigation.

For ships docking at most U.S. and European ports, it is illegal to dispose of solid waste within three miles (5 km) of shore, and for specific, sinkable types of waste, disposal needs to take place at distances ranging from three miles (5 km) to 25 miles (40 km) offshore. It also is illegal for vessels to dispose of solid plastics anywhere in the water. Ships are required to keep a log (the Garbage Record Book) describing the disposal and incineration of

countries agreed they would no longer allow oil to be discharged to the sea from ships. In 1958, the International Maritime Organization (IMO), an agency of the United Nations, was formed, and responsibility for management of the convention was transferred to that organization.

Later amended in 1962, 1969, and 1971, the convention was eventually transformed into the International Convention for the Prevention of Pollution from Ships (MARPOL, from “maritime pollution”), as modified in 1973 and 1978. MARPOL 73/78 expanded the regulation of ocean disposal of shipboard wastes from accidental and routine operations. It covers the release of chemicals and other liquids, hazardous plastic packaging materials, sewage, garbage, and air pollution via smokestack emissions. More than 160 countries as of December 2001 agreed to MARPOL 73/78. This convention is made up of 20 administrative or governing articles and five technical or regulatory annexes, as described in the table:

Although all the MARPOL 73/78 annexes have not yet been adapted by some countries, including the United States, the majority are currently enforced in ports, harbors, and shipping lanes around the world. In addition to MARPOL, there are many federal and state regulations that apply to ships operating in U.S. waters. The Clean Water Act, Port and Tanker Safety Act, and Oil Pollution Act of 1990 are, in many respects, more restrictive than MARPOL 73/78 regulations.

Both MARPOL 73/78 and other ocean pollution regulations contain exceptions related to ship safety. In the event of an emergency, the crew may take any

action it feels appropriate, including the discharge of oil or hazardous substances, to protect human life and the integrity of the vessel. Such releases can occur only after all other prudent efforts are made to correct the emergency, and they must be recorded in the ship’s log.

**Marine Shale Processors Amelia, Louisiana (1985–1994) Air Pollution** In 1985, the Marine Shale Processors Company, or MSP, received permission from the state of Louisiana to receive and treat nonhazardous oil field waste (NOW) at their facility in Amelia, about 80 miles (129 km) south-

west of New Orleans. These residues, consisting of drill cuttings from oil exploration activities, oily debris, liquids, solids, and other materials that had had contact with or been contaminated by petroleum hydrocarbons, have a higher than average British Thermal Unit (BTU) value, and are, therefore, hazardous but also a source of energy.

MSP fed nonhazardous oil field waste into a rotary kiln, where it was heated to 1,600°F (871.1°C), and the oily constituents were evaporated or burned. The kiln was a 275-foot- (84-m-) long, slowly spinning horizontal cylindrical tube. The ash and other non-combusted residue from the kiln were further processed through one of two oxidizers, or afterburners, that operated at 2,300–2,700°F (1,260–1,482.2°C), and then it was sent to a "slag box" for cooling in a water bath. These solids were then chemically analyzed to ensure that no leachable metals were present. The hot gases also were fed through the oxidizers, passed through a wet quench system for cooling, and then mixed with powdered lime to neutralize any acid that might have formed. Finally, the exhaust gas was directed through a baghouse made of racks of cloth filters to remove suspended particulate matter before discharge into the atmosphere.

The solids quenching process generated a glass-like material that MSP called slagged aggregate. MSP planned to sell this now-inert vitrified slag as filler to be mixed with cement and asphalt used as a general-purpose backfill for road, dam, and other civil engineering projects. The oily debris and related material being treated were nonhazardous, and MSP was not required to obtain a permit from the U.S. Environmental Protection Agency (EPA) as a waste treatment facility. It was also not required to meet

the very stringent air and water pollution control standards associated with the incineration of hazardous chemicals.

### **POLLUTION OF THE SITE AND REGION**

Shortly after commencing operations, MSP began soliciting industries around the southeastern United States to use its facility as an inexpensive alternative for the disposal of hazardous waste. Prospective customers were informed that MSP was a recycling business that met the definition of an industrial furnace and, as such, was exempt from regulation as a hazardous waste incinerator under the Resource Conservation and Recovery Act (RCRA). This status gave MSP an enormous competitive advantage, which was reflected in very low processing costs, and consequently they received numerous waste management orders.

Suspicious of its claims that it was a legitimate recycler, the EPA evaluated MSP's operations against a set of criteria that it had developed to identify businesses that sought to bypass the expensive permitting and monitoring requirements associated with federal oversight of hazardous waste treatment, storage, and disposal by claiming to manufacture a product. The criteria were that hazardous waste could not be accepted in excess of the amount necessary to make the product, the wastes must be stored and handled in a manner consistent with their use as a raw material, wastes could not be solicited and accepted indiscriminantly, and records must be kept documenting recycling transactions.

On the basis of data provided by MSP and the EPA's own investigations, it turned out that MSP was accepting and burning large volumes of hazardous waste that had no apparent recycling value, including spent solvents and soil contaminated with heavy metals. MSP was also accepting and storing hazardous waste in volumes far in excess of those required to produce its aggregate product. In addition, MSP accepted all types of liquid and solid hazardous wastes, regardless of their composition or BTU value. These wastes were processed without regard to the effect they would have on the finished aggregate product. The EPA also found that the hazardous wastes being processed by MSP did not have any special properties needed to make the aggregate; rather, the wastes were simply being burned for the purpose of destruction. Finally, and perhaps most important, MSP was unable to demonstrate that any of its slagged aggregate had actually been sold for use as a product.

The Louisiana Department of Transportation and Development (LADOTD) had tested the aggregate

and found it unsuitable for use in cement or asphalt purchased for state projects. The wide variation in such physical properties as abrasion resistance and water absorption made the slag behave too unpredictably, and owners and operators of cement and asphalt mills were not allowed to add slagged aggregate to their products. Without LADOTD's approval, there was no market or end use for this material.

MSP used about 320,000 tons (290,299 metric tons) of its own slagged aggregate. It used about 147,000 tons (133,356 metric tons) of the material as general fill to increase the surface elevation of a portion of its property to above the 100-year floodplain. Another 174,000 tons (157,850 metric tons) was placed as general fill on a nearby 200-acre (81-ha) site owned by an MSP affiliate company that MSP's owners planned to develop into an industrial park.

### **RESULTING LEGAL ACTIONS**

The EPA, the Justice Department, and later the federal District Court did not find that this limited use of slagged aggregate qualified it as a legitimate recycled product. The facility was ordered either to apply for a RCRA permit as a hazardous waste incinerator or to cease acceptance of all hazardous materials. As the legal proceedings ensued, the EPA continued to inspect and assess MSP's waste processing operations. The facility eventually was fined more than \$6 million for discharging pollutants in violation of Clean Air Act and Clean Water Act requirements. Finally, in 1996, with its legal options exhausted, MSP ceased operations, fired the last 200 employees, and closed the facility. The enormous piles of aggregate that had accumulated on the site were moved to its adjacent property, Recycling Park, Inc., and spread and covered with a specially designed cap to help isolate it from the environment.

In 1994, the U.S. Department of Health and Human Services Agency for Toxic Substances and Disease Registry (ATSDR) conducted a public health survey of the area around MSP, including the small town of Amelia (population 1,800) and the much larger Morgan City (population 16,000). ATSDR was unable to determine whether operations at MSP represented a public health hazard because the data were not complete. ATSDR's study found, however, that the 1993–94 air and water emissions from the plant were not at levels representing a public health concern. On the other hand, data were not available from earlier operations, before the establishment of the facility's EPA-mandated air quality monitoring program. Similarly, ATSDR could not definitively link, excess rates of spina bifida and neuroblastoma

(a type of childhood nerve cancer) that occurred in St. Mary's Parish where MSP operations were located to MSP.

Unlike many spills or uncontrolled releases of hazardous wastes, MSP operations did not result in a catastrophic event with loss of life or obvious damage to the environment. Although the public health data are inconclusive, they seem to support a finding that, at least in the short term, no adverse affects were observed in the people living near the plant. The real value of MSP as a case study is that of what did not occur. As a result of the early, aggressive action by regulatory agencies, an environmental disaster may have been averted. Once under regulatory scrutiny, MSP may have exercised more care in its operations and processes than it otherwise would have.

#### **Mason City Coal Gasification Plant Mason City, Iowa (1984–1990) Soil Pollution**

The turn of the 18th century marked the beginning of an energy revolution in the United States. Coal was cheap and plentiful and had a high British Thermal Unit (BTU) value that allowed it to provide heat for homes and power the blast furnaces and mills that produced the steel, iron, and finished goods

of the country's nascent heavy industrial sector. In contrast, coal was difficult to transport, and storage space, especially for large quantities, took up precious room in both homes and factories. It was dirty and left a black, carbonaceous residue on everything it touched. When coal burned, the smoke and ash produced were thick and a threat to public health. This was especially true in congested urban centers, where coal not only powered industry but also heated homes and cooked meals.

It had been known since the 1700s that if coal is heated (distilled) in the absence of oxygen, it forms coal gas, a highly flammable mixture composed primarily of hydrogen (50 percent), methane, carbon monoxide, and traces of other gases. Although coal gas had obvious benefits, it was not commercially available until 1805. In 1816, the city of Baltimore, Maryland, was awarded the first large contract in the United States to manufacture coal gas and install distribution piping so the city could use it for streetlights. A few years earlier, textile mills in Rhode Island and Massachusetts had begun lighting their facilities by using coal gas and, as a result, local coal gas companies were springing up all over the country, producing gas from plants primarily made from kits manufactured in New York City. By 1860, almost 300 manufactured gas companies were in operation and served approximately 5 million customers. Larger and more complex facilities were soon constructed to accommodate the ever-increasing demand for gas. As the smaller companies were eliminated from the market, eventually about 1,500 manufactured gas plants would dominate the supply industry. These plants heated coal and even oil to make gas using a variety of processes; two of the most common were the carbureted water gas and oil-gas methods.

The carbureted water gas process involved injecting a small amount of oil into a heated vessel of distilled, moist coal gas. The oil and moisture-rich coal gas combined, forming a fuel that had a high thermal (BTU) content. This enriched form, called blue gas, burned hotter and cleaner than other forms of coal gas, and this process soon was the process of choice for the manufactured gas industry in the United States. A carbureted water gas plant consisted of a brick-lined, cylindrical steel vessel called the generator, where the coal was cooked to produce the gas. From the generator, the gas went to the carburetor (carbureter), where it was physically mixed with oil. It then passed to a superheater, where the oil was thermally bonded, or "fixed," to the gas. Flowing beside a wash box, the moisture in the gas was allowed to condense and impurities settled out. The carbureted water gas would be passed through

Modern coal gasification plant in Beulah, North Dakota (David R. Frazier Photolibrary, Inc./Alamy)

a series of filters to remove remaining impurities before being discharged into a storage chamber that provided a continuous gas supply to the exhauster. The exhauster held the final gas-purifying equipment, and from there it flowed to the storage holder for eventual entry into the plant's distribution system and delivery to the customer.

The oil-gas process used liquid petroleum as its raw material instead of coal. First perfected in the late 1890s, the process was similar to the carbureted water gas method in that oil was steam heated in a generator vessel to release the gas. This gaseous mist then was sent to a vaporizer, where additional water was added before routing to the superheater. After leaving the superheater, the gas was purified and processed for distribution in a manner very similar to that for carbureted water gas.

The 1920s was the peak of manufactured, or "town," gas and manufactured gas plants (MGPs) in history. As manufactured gas had replaced coal, liquid oil and natural gas began slowly to supplant coal gas as the nation's energy source. At the end of World War II, manufactured gas was being phased out in favor of cheaper and cleaner-burning petroleum products, and, by the mid-1950s, MGPs had largely disappeared as part of the U.S. energy infrastructure.

### POLLUTION AT MGP PLANTS

As with any industrial process, MGPs produced residues and by-products, whether from simple coal gasification or the more complex carbureted water or oil-gas methods. These by-products were known as coal tars, and they were often left behind in soils and subsurface tanks and enclosures when the plants were closed. Coal tars and other MGP residues are toxic, and many are known or suspected carcinogens. These residues contain polycyclic aromatic hydrocarbons (PAHs) such as pyrene, phenanthrene, chrysene, anthracene, and benzo(a) pyrene, as well as benzene, creosote, cyanide, heavy metals, and phenolic compounds. Their presence in soil at former MGP sites can pose both significant public health and ecological risks. MGP residues can leach to contaminate groundwater or become airborne during site redevelopment activities. This causes particular problems, as many of the former MGP site operators simply went out of business and abandoned their plants with large amounts of wastes and residues remaining in the process vessels. Others were purchased by public utility companies, which demolished the surface facilities, redeveloped the land, and were unaware of the buried toxic residues left behind by former MGP operations.

### **Example of Mason City, Iowa**

One example of this type of problem is the Mason City Coal Gasification Plant Superfund Site, which is located on approximately 2.3 acres (0.9 ha) in a commercial and residential area of central Mason City. A north-central Iowa community of 29,000, Mason City is 220 miles (354 km) west of Sioux City. Between 1900 and 1951, an MGP plant operated to produce gas for lighting and heating. The plant was demolished in 1952 when natural gas service became available. Residues from coal gasification were buried on the site, along with some of the more heavily contaminated components of the plant. The land was acquired by Alliant Energy Corporation (formerly Interstate Power Company), which constructed a small electrical substation and storage shed on the property.

In 1984, Mason City negotiated an easement across the edge of the site to install a new sewer line. When excavation commenced, workers discovered an oily sludge, called coal tar, in subsurface soil at the site. Subsequent investigations by the site owner uncovered three underground storage tanks (USTs), also containing coal tars. The tanks and associated contaminated soil were excavated, but more contaminated soil was found in the north-central portion of the property.

The groundwater table is relatively shallow, only eight to 10 feet (2.4–3 m) below the surface, and the property's northern side is bounded by Willow Creek. This posed two environmental concerns: (1) that leachate from the site would discharge into Willow Creek and contaminate surface water and sediments, and (2) that coal tar residues would migrate downward and contaminate the underlying limestone aquifer (karst) that provides Mason City's drinking water. Eight Mason City municipal drinking water wells are within two miles (3.2 km) of the former MGP site.

### **THE CLEANUP**

To address soil contamination on the property, remedial actions included excavation of soil exceeding action levels. These action levels, based upon concentrations of certain PAHs present in the soil, were determined on the basis of the likelihood of contaminant exposure and the effects such exposure would have on sensitive people such as children, elderly adults, and infirm people. Once excavated, the contaminated soil and recovered wastes were sent to an off-site treatment facility for thermal desorption of adsorbed pollutants. More than 21,000 tons (19,051 metric tons) of material was processed by low-tem-

perature thermal desorption. After posttreatment sampling confirmed that these materials contained PAH concentrations below action levels, the soil was returned to the on-site excavation, compacted, and covered with a layer of topsoil and asphalt. This process eliminated the environmental and public health threat posed by the coal tar-contaminated materials.

During the soil removal action, however, several areas were identified where the levels of contamination exceeded the action levels but the soil could not be removed. These included soil near and underlying the power substation, beneath the sewer line that traversed the site, and beneath some subsurface concrete structures in the corner of the property. To ensure that these areas would not pose a future threat to groundwater, a long-term monitoring program was implemented and a contingency plan developed to control the migration of contaminants hydraulically, if they were found to be moving off-site or deeper into the water supply aquifer. A deed notice also was filed with the Mason City property tax and zoning offices that would alert future landowners to the presence of the treated and untreated soil and prevent the site from being used for residential or other sensitive purposes. The cost of the investigation and cleanup of this small site exceeded \$2 million.

### **A BIGGER PROBLEM**

The Mason City former MGP site situation is not unique and illustrates many of the problems that face former MGP property owners as well as the federal and state environmental agencies that regulate them. MPGs were widespread throughout the country, and, as the businesses failed, many of the sites simply were abandoned, demolished, or redeveloped and sold by their new owners, who did not realize the dangers that were buried beneath the ground. Over time, records that indicated the presence and operation of these facilities were lost, and many were only rediscovered by accident, as in the case of Mason City, or through a diligent search of historical land use maps or city directories. Many of the new property owners do not have the financial resources to address the cleanup of an MGP site, which can run into millions of dollars. Those former MGP properties owned by gas and electric utility companies, which were very active in the 1940s and 1950s in the purchase and phaseout or retooling of MGP operations, face extensive remedial obligations, often for more than one property. These obligations must be prioritized on the basis of the environmental and public health risks each site poses

and associated cleanup costs then passed along to the rate-payer.

**mass wasting** Mass wasting is the movement of any material down a slope on the surface of the Earth. By definition, every slope is metastable, continuously seeking to flatten itself. The ultimate cause of mass wasting is the Earth's gravity. There are two vectors of force that are resolved from the gravitational force imposed on an object on a slope. One resolved vector is of normal force; it holds the object fixed on the slope; the other is a shear force, which drives the object down the slope. The combination of normal force and friction on the slope that acts against the shear force keeps the object in place. These forces combine to define a maximal slope angle that a material can retain, above which it fails. This is defined as the angle of repose, and it is unique for both the material and the conditions under which it exists. If the conditions change, then so does the angle of repose.

If sand is dumped onto a table, it makes a cone-shaped pile with the same slope angle on all sides. If more sand is added, the sand pile grows, but the slope angle remains the same. This is because the slope of the pile is at the angle of repose for

"Time and the river flowing . . ." is an example of how the Colorado River and mass wasting can form such magnificent landscapes as these massive exposures of the Red Wall limestone within the Grand Canyon. (AP Images)

**Chart showing the various types of soil and debris mass movements and the velocity and water content of each**

those conditions. The slope does not keep the angle constant, if water is added to the sand, the angle of repose increases to near-vertical as the result of capillary action among the sand grains. This is why sand castles may be built at the beach. If water is added to the point of saturation, the sand flows, cannot maintain steep angles, and fails quickly. Ground shaking, as during an earthquake, reduces the angle of a slope, whereas planting trees, rerouting drainage, and building retaining walls all increase the angle of repose, the maximal stable slope.

### CLASSIFICATION OF MASS MOVEMENTS

Mass movement of slopes can be classified by processes of failure and transport. The main subdivision for classification of mass movements is based upon material. Solid rock slope failures use a separate system from the movement of soil and surficial materials. The following is a list of the different types of mass movements:

- *Rock failures* of faces on cliffs and slopes is based purely on the way the material falls. The release of the rock does not play a role in the classification but can result from an abrupt event such as an earthquake or a prolonged event such as the freezing and thawing of water in cracks (frost wedging).
- *Rock falls* involve the breaking away and free fall of rock from a cliff to the ground below. The movement is high speed and results in deposition of talus, or rock debris, at the base of the slope.
- *Rock slides* involve the breaking away of rock and sliding down a slope, usually along bedding or another surface that characterizes the rock unit. Rock slide also produces talus deposits. Other rock movements are variants of these two.
- *Rock topples* involve the breakage and rotation of a rock body into a free fall similar to a rock fall, for example.
- *Soil and debris failures.* The general term *landslide* captures many of the subdivisions of soil and debris slope failures. Basically, the amount of water in the material, the speed of movement, and whether the material is coherent or fragmented are the three factors in the classification of these failures. With less than 20 percent water, the fastest failure is a debris avalanche, which may begin as a rock or debris fall and gain speed. These mass movements contain rocks, trees, and other debris and travel at speeds of 60 miles (96 km) per hour to more than 250 miles (400 km) per hour. Grain flows are similar in composition but travel at slower speeds, between 60 miles (96 km) per hour and 325 feet (100 m) per hour. Earth flows are classic landslides with a coherent mass sliding down a slope at 325 feet (100 m) per hour to as slowly as 0.5 inch (1 cm) per year. Slower than this is the process of creep.

**Angle of repose for piles of several types of sediment: It is the maximal slope angle before the sediment slides down the hill.**

**Block diagram showing slumping, a type of landslide**

Block diagram showing a rockfall from a cliff with a talus slope or pile at the base

If the material in the mass movement contains between 20 and 40 percent water and the speed is 250 miles (400 km) per hour, it is called a slurry flow. Less than this speed but faster than 0.63 mile (1 km) per hour is a more common and generally more devastating mudflow. Debris flows are a bit more cohesive than mudflows but slower at 0.63 mile (1 km) per hour to 0.5 inch (1 cm) per year. They can also cause great damage. Solifluction is the slowest of the wet flows, at less than 0.5 inch (1 cm) per year.

### POLLUTION CAUSED BY MASS MOVEMENTS

There are a range of types of pollution caused by mass movements; they are largely pollution caused either directly by the slope failure or indirectly by things destroyed by the failure. Direct pollution is primarily the result of material moving into a stream, river, or other water body. The added material causes siltation of the river, which can be

muddy for days or even weeks after the failure. If such a failure affects a reservoir, it can render the water undrinkable for a time. These situations can occur with any type of mass movement. Significant amounts of particulate air pollution can be generated directly by an avalanche, typically in the form of powdered rock, or “rock flour.” Debris flows and mudflows expose soil to the elements. If the surface dries out and is swept into the air by wind, it can also generate pollutants.

Probably the main failure that causes direct pollution is from a mudflow. This sort of massive river of mud can flow down slopes and through towns, inundating everything. The forward force a thick flow generates can burst through the walls of any building and crush smaller and weaker buildings. They inundate the inside of the buildings after a collapse. Their great weight can cause sewers to back up and overflow; that overflow with the mud can infiltrate surface water supplies. In this way, the flow can promote disease. After the flow settles, the typically

organic-rich mud can decay, adding to the cleanup, which can take weeks to months of full-time effort before it is complete.

Mass movements can destroy virtually any structure in a variety of ways. It is the job of civil and geotechnical engineers to anticipate these problems and plan accordingly. Their efforts can be observed on the slopes on the sides of highways nationwide. Any of the rock failures and high-speed slope failures can destroy structures as a function of the size of the failure and structure. These structures might be above-ground storage tanks, pipelines, rail lines with tanker

cars on them, manufacturing plants, and power generating plants. Spills of any number of chemicals are possible from such events, which aid in spreading the pollution with their continued movement.

Unlike many other natural disasters, slope failures may also rupture underground structures. They can unearth pipelines and underground storage tanks if they are on slopes that fail. If they are undermined, they can rupture or even slide down the slope, producing a chemical spill. Not only will the spill be spread by the mass movement; it can also flow down the slope. If a Superfund site sits on a hillslope, it

**Block diagram of inclined layers of rock and a rockslide or debris slide along them**

**Block diagram showing creep mass movement and some results of features on the slope such as a J-shaped tree (A), fallen gravestone (B), tilted utility pole (C), drifted fence line (D), shifted road (E)**

too may be disrupted by a mass movement, causing a potentially even more dangerous situation. If gas lines are ruptured, a gas leak can cause local air pollution and a significant risk for explosion. In earthquakes, one of the main causes of hazardous chemical spills is mass movement.

Another, less common result of a mass movement is from a tsunami. In 1957, an earthquake shook loose an avalanche in Lituya Bay, Alaska. The avalanche hit the water in the bay with such force that it generated a wave that climbed 1,700 feet (523 m) up the facing side of the bay, stripping it of trees, other plants, and soil. This is the largest wave ever recorded. There is good documentation of other tsunami waves that were generated by underwater landslides, notably in the Philippines and eastern Canada. A similar situation occurred in a reservoir behind the Vaiont Dam on the Pieve River, Italy, in 1963. A rock slide into the reservoir occurred after a particularly heavy rainstorm. The volume of rock displaced so much water that the reservoir level topped the dam and generated a 650-foot- (200-m-) high wave that devastated the valley, killing some 3,000 people. These occurrences add all of the

environmental hazards of a tsunami strike to those generated by the mass movement, causing even more damage.

**MBK (methyl butyl ketone)** Commonly known as 2-hexanone and propyl acetone, MBK is an odd pollutant in that it was formerly produced for use in commercial products. It was found, however, that the adverse health effects on the workers and threats to public health far outweighed the benefits, and its use slowly waned to the point that it is no longer produced or even used much in the United States. This should have eliminated MBK from concern, but that is not the case. MBK is also an unwanted waste product of many industrial processes including wood pulp production, coal gasification, and oil shale processing. It is, therefore, quite plentiful in certain areas. MBK has been ranked as the number 72 worst environmental threat of the 275 chemicals on the 2007 CERCLA Priority List of Hazardous Substances, and it has been found in 199 of the first 1,416 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List) where it was tested. Considering the limited availability of MBK, this is a very high ranking, reflecting the danger posed by the adverse health effects.

### PROPERTIES, USE, AND PRODUCTION

MBK is primarily a synthetically produced organic hydrocarbon solvent, but very small amounts also occur naturally in some foods such as cheese, nectarines, nuts, bread, milk, cream, and chicken, among others. In its pure form, it is a clear, colorless liquid with a sharp acetone-like smell. MBK was commonly used as a solvent in several applications, including paints, lacquers, ink thinners, nitrocellulose, glues, resins, oils, fats, and waxes, and in printing of plasticized fabric. It was also used as an evaporating solvent for nitrocellulose acrylates, vinyl, and alkyd coatings. One source claimed that domestic production of MBK was less than 1,000 pounds (454 kg) by 1975, but it could not be verified.

### ENVIRONMENTAL RELEASE AND FATE

MBK is primarily a point source pollutant from current wood pulp, coal gasification, and oil shale operations and from leakage from older toxic waste sites. MBK evaporates readily, so release to the atmosphere, either directly or indirectly, is significant. Once in the air, MBK is degraded quickly with a removal half-life of about two to three days by reaction with photochemically produced hydroxyl radicals. Minor amounts may also be returned to the Earth in precipitation as washout. If it is released into the soil, a significant amount evaporates from the surface in both wet and dry conditions. That which penetrates the surface is mainly broken down by soil microbes.

Experimental tests indicate that up to 60 percent of MBK may be removed in five days by biological action under certain conditions. Normally, the process is slower. MBK is relatively mobile under most soil conditions and may be leached into the groundwater system, where it may persist for longer periods. MBK has been found in groundwater systems near waste sites and oil shale or coal gasification facilities in Florida, New Jersey, Delaware, Michigan, Wyoming, New York, Quebec, and West Virginia, among other locations. If it is released into surface waters, evaporation is, again, the primary mode of removal. Experimental studies indicate that the removal half-life by vaporization is seven hours for a river and 164 hours for a lake, depending upon conditions. Some studies claim that it can persist for 10–15 days in rivers. MBK has been detected in Lake Erie, among other surface water bodies. That which is not evaporated may adsorb to certain particles in the water and settle into the sediment, where it may persist for long periods depending upon bacterial action. MBK will not bioconcentrate in plants or organisms.

### HEALTH EFFECTS FROM EXPOSURE

Exposure to MBK has been found to cause several adverse health effects. Acute exposure to its vapors at moderate levels produces transient eye and nasal irritation. Some eye damage from it can be permanent. Continued exposure to it produces central nervous system effects, including fatigue and sleepiness, followed by weakness, loss of coordination, and numbness and tingling in the hands and feet. Long-term chronic exposure to it may result in inability to walk, minor paralysis, reduced immune function, and possible long-term to permanent neurological damage. Pregnant animals that were exposed to MBK were found to have fewer surviving offspring and lower birth weights.

### REGULATIONS ON HUMAN EXPOSURE

MBK is regulated only by federal agencies that are concerned with the health and safety of workers. The Occupational Safety and Health Administration (OSHA) set a limit of five parts per million (ppm) of MBK in workplace air (PEL) during an eight-hour workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) set a more stringent limit (REL) of 1 ppm for a 10-hour day, 40-hour workweek and immediately dangerous to life and health (IDLH) concentration at 1,600 ppm. The NIOSH National Occupational Exposure Survey of 1981–83 estimated that 1,778 workers were exposed to MBK in the United States.

**McKin Disposal Company Gray, Maine (1972–1985) Water Pollution** Although known primarily for its picturesque shorelines, forests, and rustic lifestyle, the state of Maine plays an important role in the trade, service, and finance sectors of the U.S. economy. Maine is a major producer of paper and wood products and is an important center in the manufacture of transportation equipment. Industrial minerals such as granite, sand and gravel, zinc, and peat also contribute to the state's economic output. Bath Iron Works, one of the largest builders of complex, technologically advanced naval ships in the country, is Maine's largest employer. Many of the raw materials and fuel for these and other commercial activities that take place throughout Maine enter the state through Casco Bay.

Portland, the largest city in Maine, lies on the southwest coast of Casco Bay. The bay is a commercial shipping channel, tourist attraction, and fishery. Timber, minerals, and finished goods pass through Casco Bay to and from Canada and the lower East Coast and to the port of Portland for off-loading and transshipment westward. The bay and its associated 1,000 miles (1,609 km) of adjacent watershed include 25 percent of Maine's population and host annual commercial and industrial businesses, fisheries, shellfish, and recreation/tourism activities worth almost \$500 million.

Like other working ports, Casco Bay is struggling to maintain its environmental quality. Most recently,

it has been seeking to balance the impacts of nearby growing population and regional economic expansion with negative impacts to surface water and air quality. Forty years ago, however, a more fundamental assault on the bay occurred; it helped shape how environmental cleanups would take place across the United States.

#### THE OIL SPILL

In the early morning of July 22, 1972, the Norwegian tanker M/V *Tamano*, chartered to Texaco Inc. and loaded to capacity with no. 6 fuel oil (also called Bunker C), was making its way slowly and carefully through Casco Bay toward Portland. Onboard were an experienced crew and a licensed harbor pilot; the weather was clear and the channel well marked. It was for this reason that it was a complete surprise when the ship struck a submerged outcrop of granite called Soldier Ledge. The collision tore a hole in the hull and 100,000 gallons (378,541 L) of heavy industrial fuel oil promptly spilled into the waters of Casco Bay. One of the major causes of the grounding was eventually linked to a buoy that had been moved or had drifted and falsely marked Soldier Ledge as part of the shipping channel. Cleanup operations including off-loading of oil that remained in the tanker were delayed for several hours as industry and government officials argued over who was responsible and who would be in charge.

Bunker C is a fuel oil used to fire large industrial boilers. It is viscous and produced by blending heavy petroleum residues with lighter oils. Once spilled, Bunker C is very persistent, with only 5–10 percent expected to evaporate within the first few hours of entering the water. It tends to break up into discrete patches called tar balls, rather than forming extensive slicks. These tar balls can be a few inches to several tens of feet in diameter and can be carried hundreds of miles from the spill site by currents or winds. Fortunately, because of their density, once these tar balls make landfall, they tend to stay on the surface of the beach and are relatively easy to identify and scoop up. In the case of the Casco Bay spill, the cleanup took several months and cost millions of dollars, most of which was paid by the *Tamano*'s insurers.

The wreck of the *Tamano* did not result in far-reaching or long-lasting environmental consequences. The spill was addressed, and, fortunately, ecological damage to beaches and wildlife was kept to a minimum. The real impact to Maine's environment did not result from the *Tamano* spill but from its cleanup. More specifically, the coagulated Bunker C was skimmed from Casco Bay and scraped off its beaches properly; the problem occurred when it was sent to the McKin Company disposal facility.

## BACKGROUND

About 30 miles (48.3 km) north of the *Tamano* spill and 15 miles (24.1 km) north of Portland, a seven-acre (2.8-ha) sand and gravel pit was located just outside the small Maine town of Gray. For many years, the sand, gravel, silt, and clay had been excavated for use as local building materials, primarily by cement and construction companies. The pit varied in depth, between 6 and 20 feet (1.8–6.1 m) deep. When the sand and gravel were exhausted, the McKin Company purchased the site. Starting in 1964, McKin began operations as a tank cleaning and waste removal company. McKin sent tanker trucks and service crews to industrial facilities throughout New England to clean out chemicals and process tanks and take the wastes back to their Gray facility for processing. The property was used for the collection, storage, disposal, and transfer of petroleum and industrial chemical waste.

The facility underwent a major expansion in 1972 in order to handle wastes from the *Tamano* spill. An incinerator was installed to burn Bunker C contaminated soil and cleanup residues. This incinerator was supported by other waste management facilities, including an asphalt-lined treatment lagoon, 22 aboveground storage tanks, and storage pads for drummed wastes. Between 1972 and 1977, McKin processed between 100,000 and 200,000 gallons (378,541–757,082 L) of liquid waste per year, making it the largest waste processing facility in New England and one of the largest in the eastern United States.

## THE POLLUTION

By 1973, nearby residents knew something was wrong. Water from their wells smelled funny and was staining their laundry and sinks. Subsequent investigations by the U.S. Environmental Protection Agency (EPA) quickly confirmed the contamination of local private wells, and, as a result, connected nearby residents to the public water supply system. The source of this contamination was related to McKin's operations. Apparently, McKin was processing much of the waste it accepted for disposal by pouring or spreading it on the ground. The soil cover was so thin, as the overlying sand and gravel had long since been removed by quarrying operations, that the chemicals had only to migrate a few feet into the ground before they entered the groundwater.

## THE CLEANUP

In 1979, the Maine Department of Environmental Protection, working with the EPA and private contractors, removed more than 33,000 gallons

(124,919 L) of wastes and 165 drums of oils and chemicals from the site. Removal of all the waste was not completed until 1985, and McKin, along with 12 other sites in Maine, was added to the National Priorities List as a Superfund site. The removal actions alleviated the worst of the near-term environmental threat from the site, but surficial soils were still grossly contaminated with volatile organic compounds (VOCs), primarily trichloroethane (TCA) and trichloroethene (TCE); petrochemicals; and heavy metals, including arsenic, lead, and mercury. The concentrations of these compounds in the soil were a continuing source of contamination to the groundwater. In 1985, EPA selected low-temperature thermal desorption (LTTD) as the preferred remedy for the contaminated soil at McKin.

LTTD is an ex situ low-temperature, incineration-type process that is used on more easily treated contaminants. This technique, also called thermal desorption (TD), or soil roasting, is most commonly used to treat soil containing gasoline, solvents, and other petroleum compounds. These types of materials can be heated at relatively low temperatures in the range of 200–600°F (93.3–315.6°C), and the petroleum or other organic constituents are volatilized and driven out of the soil. The fumes are collected and treated by being either absorbed onto carbon, run through a catalytic converter, burned in a high-temperature incinerator, or, depending on their concentrations, discharged directly into the atmosphere. After roasting, the soil retains much of its original organic content, although most of its moisture is removed. With some reconditioning, the roasted soil can be reused.

If the contaminants are more complex with longer-chain hydrocarbons such as PCBs or pesticides, high-temperature thermal desorption (HTTD) can be used. In HTTD, contaminated materials are heated to 600–1,000°F (315.6–537.8°C). Both systems are designed not to change the chemical composition of the contaminants but simply to volatilize them or convert them from a solid or liquid to a gas. If oxidation occurred in either LTTD or HTTD systems, then thermal desorption would really be incineration.

At the McKin site, more than 12,000 cubic yards (9,175 m<sup>3</sup>) of contaminated soil was excavated, passed through a coarse grate or sieve, and fed with some water into a rotating cylindrical drum seven feet (2.1 m) in diameter and 28 feet (8.4 m) long. Hot air heated the soil in the cylinder to 400°F (204.4°C). It took up to three passes through the burner for the soil to achieve the cleanup requirements. Exhaust gases from the burner were passed through a high-efficiency particulate air (HEPA) filter to remove smoky particulate, a baghouse to remove coarser

particulate, a scrubber to remove water-soluble chemicals and remaining particulate, and, finally, a carbon filter to remove trace amounts of organic chemicals. Treated soil was mixed with cement to reduce any remaining contaminant mobility, and it was redeposited at the McKin site. Costs for treating this soil totaled around \$3 million, which was paid by the companies that had sent the waste to McKin for disposal, including the *Tamano* insurers.

Soil roasters or burners can be either fixed facilities, where soil is sent either by truck or rail, or mobile facilities, which travel to the contamination. In most cases, the amount of soil has to be quite large before mobile soil burning becomes a cost-effective remedial option. The system used at McKin was a rotary dryer, which is an inclined, indirect-fired horizontal cylinder, where heated gas was mixed with the soil to desorb the contaminants. Direct-fired units apply a steady flame to the surface of the soil to desorb the contaminants.

Wastes from the *Tamano* had to be remediated twice, once after the spill and once again because of inadequate processing by the disposal company. Both public and private resources had to be committed to clean up the waste twice, with a double toll on the environment, affecting surface water and shorelines in Casco Bay and the groundwater in Gray. This led to several administrative and procedural changes by the EPA and many states regarding the management of remediation-generated wastes. Contaminated debris and material recovered from a spill or discharge now can only be sent to preapproved waste management sites. Regulatory agencies, insurance companies, or waste generators audit these facilities to ensure that they are in compliance with all environmental regulations; are not connected to organized crime; do not have ongoing, controlled releases into the environment; and have all necessary operating permits.

**MEK (methylethyl ketone)** Although methylethyl ketone is not very toxic in comparison with many of the other pollutants, it is very widespread. In contrast, its close relation, methylethyl ketone peroxide (MEKP), is far less widespread but far more toxic. MEK is also known as 2-butanone, ethyl methyl ketone, methyl propanone, and methyl acetone; MEKP is known as 2-butanone peroxide and methyl ethyl ketone hydroperoxide. Commercial names for products containing MEKP include Butanox, Cadox, Chaloxyd, Esperfoam, Hi-Point, Kayamek, Ketonox, Lupersol, Mekpo, Permek, Quickset, and Thermacure. There are far too many products that contain MEK to list all of them. MEK has been ranked as the 208th worst environmental threat of the 275 chemicals on the 2007 CERCLA Priority List of Hazardous Substances. It has been found in 472 of the first 1,416 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List) where it was tested. MEKP has too little usage to be listed even though it is far more dangerous. Both compounds are described and contrasted.

#### PROPERTIES, USE, AND PRODUCTION

MEK is primarily a synthetic organic compound that occurs as a colorless liquid with a sharp, acetone-like odor. It occurs naturally in fungi, some trees, and some fruits and vegetables, as well as in tobacco smoke, volcanic emissions, and forest fires. MEKP has similar physical features, except that it is typically slightly yellow, not produced in nature, and quite explosive. MEK is primarily used as a solvent for lacquers and adhesives, for cleaning materials in electroplating, in manufacturing magnetic recording tapes, in rubber and rubber cement, and in printing inks, paints, waterproof-

ing compounds, surface coatings, shoe polish, insecticides, nail polish and nail polish remover, wood stains, varnishes, cleaning solutions, extraction solvents, and paint removers. It is used as a sterilization solvent in the medical industry, in oil dewaxing and as a synthetic agent in the pharmaceutical and cosmetic industries. MEKP is widely used in the polymer industry for curing polyester resins. It is used primarily for boat building and repair, household furniture, pressed and blown glass, transportation equipment, and in supply and stone and tile products.

MEK is a high-demand chemical with an annual production of more than 675 million pounds (307 million kg) in the United States alone in 2002. MEKP, by contrast, is a compound that has much lower production with 5.9 million pounds (2.68 million kg) produced in 1982.

### ENVIRONMENTAL RELEASE AND FATE

Both MEK and MEKP are primarily released into the environment as point source pollutants, if from anthropogenic sources. They are inadvertently released from manufacturing, transport, and storage facilities as spills and leaks. Natural MEK and that from automobile exhaust and smoke are largely released as nonpoint source pollutants. Most MEK winds up in the atmosphere from both exhaust and smoke, and through its ready evaporation. The removal half-life of MEK in the air is 2.3 days as the result of reactions with photochemically produced hydroxyl radicals. It may also be removed by direct photolysis, with a half-life of 15.4 hours, and by precipitation washout. If it is released into water, the vast majority of MEK evaporates, and the rest is broken down by microorganisms in about two weeks. Most MEK released into soil also evaporates, but that which does not is highly mobile. Very little adheres to soil particles, leaving most to leach into the groundwater system or be broken down by soil microbes. MEK has been shown to inhibit the germination of lettuce seeds and wheat seeds by 50 percent or more. It is also toxic to the Caribbean fruit fly and somewhat toxic to other insects. It has long-term toxicity to aquatic life but is otherwise relatively benign. There is very little known about the release and fate of MEKP, but it is generally assumed to behave similarly to MEK in terms of interactions with air, soil, and water.

Annual releases of MEK into the atmosphere in Canada increased from 3,692 tons (3,356 metric tons) in 1993 to 4,872 tons (4,429 metric tons) in 1997.

### HEALTH EFFECTS FROM EXPOSURE

Both MEK and MEKP show a variety of adverse health effects, with the latter far more toxic. Acute exposure to MEK produces nose and throat irritation through inhalation and effects on the central nervous system such as intoxication, nausea, headache, dizziness, sleepiness, fatigue, and confusion through both ingestion and inhalation. At extreme concentrations, symptoms can be loss of consciousness, pulmonary edema with lung exposure, respiratory failure, cardiac arrest, and death. It is also a moderate to severe eye irritant and a skin irritant. Long-term chronic exposure can result in numbness in the fingers and toes, decreased nerve conduction, chronic headaches, dizziness, dermatitis, gastrointestinal distress, loss of appetite, weight loss, and muscle atrophy. Laboratory animals showed minor effects on the brain, liver, kidney, and spleen, as well as changes in blood chemistry. There is also some evidence of fetal toxicity and adverse developmental effects. It requires very high concentrations of MEK alone to produce these adverse health effects. MEK also appears to have a metabolic interaction with n-hexane, carbon tetrachloride, chloroform, and methylbutyl ketone, enhancing their neurotoxicity significantly, as well as potentially damaging the liver and lungs. MEK is classified in group D, not classifiable as to being a human carcinogen.

MEKP causes much more severe symptoms at much lower dosage than MEK. Taken internally, MEKP causes chemical burns of the gastrointestinal tract, scarring of the esophagus, hyperemia of the lungs with hemorrhaging, pulmonary edema, and mild liver and kidney damage. Through inhalation, it causes irritation of the nose and throat, labored breathing, abdominal pain, vomiting, diarrhea, and many of the symptoms produced by ingestion. Contact with vapors can cause irritation of the eyes and skin. Higher dosage typically results in coma and death through cardiac arrest, hepatic failure, and other complications. It can also cause permanent damage to the eye and, through contact with liquid, even blindness. Long-term exposure has been shown to increase the likelihood of malignant tumors in many locations of the body.

### REGULATIONS ON HUMAN EXPOSURE

Although the EPA does not have any guidelines for MEK or MEKP in water under the Safe Drinking Water Act, the EPA and other federal agencies have a variety of other regulations on both compounds. The EPA requires the reporting of discharges or spills of 5,000 pounds (2,272 kg) or more to the National Response Center. The Occupational Safety

and Health Administration (OSHA) set a limit of 200 parts per million (ppm) of MEK in workplace air (PEL) during an eight-hour-workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) set the same general limit (REL) as OSHA but with a short-term exposure limit at 300 ppm and immediately dangerous to life and health (IDLH) concentration at 3,000 ppm. In comparison, OSHA and NIOSH initially concurred on an exposure limit (PEL and REL, respectively) of 0.2 ppm in workplace air during a regular workweek, but OSHA revised their limit to 0.7 ppm. The NIOSH National Occupational Exposure Survey of 1981–83 estimated that 25,800 workers were exposed to MEKP in the United States.

#### melamine (1,3,5-triazine-2,4,6-triamine)

Under normal circumstances, it is unlikely that melamine would have been included in this compilation. It is of relatively low toxicity and is not included in the 2007 CERCLA List of Hazardous Substances or any other top pollutant list. It is not tracked in Superfund sites, and there are no descriptions of it or its effects available from the National Institutes of Health, U.S. Environmental Protection Agency (EPA), or any of the other federal regulatory

agencies. The only reason that it is included is that it was identified as the culprit in a major poisoning scandal of pet foods in spring 2007. After many pets were sickened or died after ingesting pet food from China, melamine was identified as the cause, but under unusual circumstances. This entry will present the general background of melamine, and then it will describe and discuss the causes of the poisoning incident and its repercussions.

#### PROPERTIES, USE, AND PRODUCTION

Melamine is a cyanamide, a nitrogen hydrocarbon, that is synthetically produced or a metabolite of cryomazine pesticide. It does not occur naturally. Melamine was first synthesized in 1834 but was not heavily used until relatively recently. The main use of melamine is in the production of melamine resins, which are almost exclusively used in industrial applications. These resins are used in the production of laminates for tabletops, school furniture, and the like; glues, adhesives, molding compounds, coatings, paper, superplasticizers for concrete; and the addition of properties of shrink resistance, water and stain repellence, and flame retardance to cloth. Melamine itself is used also as a flame retardant in polyurethane foams, in fire retardant paints, and in the production of fertilizers, yellow pigment for inks and plastics, and some pharmaceuticals. Melamine was used as a nonprotein nitrogen for cattle from 1958, but a 1978 study concluded that it was inappropriate for health reasons, and the practice was dropped in the United States. Currently, China is the largest producer and consumer of melamine.

Melamine is also known as 2,4,6-triamino-*s*-triazine, cyanuric triamide, cyanurotriamine, isomelamine, and *s*-triaminotriazimine, among others.

#### ENVIRONMENTAL RELEASE AND FATE

Melamine is primarily released into the environment as a point source pollutant from accidental spills and leaks during manufacture, transport, storage, and disposal. Improper disposal also releases melamine to the environment. If it is released into the soil, most melamine does not readily adhere to soil particles, and, as a result, is relatively mobile. Melamine largely degrades by nitrification, which has been shown to occur at a rate of 18 percent in six to 24 weeks depending upon conditions. The removal half-life of melamine from soil through all removal processes is about two to three years, a very slow rate. Although melamine is removed from activated sludge in a wastewater treatment plant in eight hours, in natural conditions, it is very slow to be

removed from surface water. Melamine is removed from air by fallout and washout by precipitation. The toxicity of melamine to mammals and aquatic organisms is considered low.

The NIOSH 1981–83 National Occupational Survey estimates that 44,648 workers were exposed to melamine in their place of work.

### HEALTH EFFECTS FROM EXPOSURE

Melamine is considered to be of low to very low toxicity. Acute exposure may produce irritation of the eyes, skin, and mucous membranes. Long-term exposure can result in dermatitis, weight loss, elevated fluid intake, chronic inflammation of the kidneys, ulceration and hyperplasias of the urinary bladder, development of urinary bladder stones, calcareous deposits (and stones) in the kidneys, and possible reproductive effects. The International Agency for Research on Cancer placed melamine in group 3, not classifiable as to its carcinogenicity to humans. Tests on laboratory animals, however, produced in some species an increased incidence of cancer of the bladder. The problem with all of these tests is that the doses required to produce the adverse health effects are far greater than any environmental levels and, in most cases, even higher than industrial exposures. It was further found that addition of table salt to the diet would reduce the incidence of cancer from melamine exposure.

### 2007 PET FOOD INCIDENT

In March 2007, pets across America became deathly ill. They stopped eating and experienced pain with symptoms of kidney failure. Their illness was quickly traced to pet food imported from China. At first, it was thought that wheat gluten filler was the culprit, but melamine was discovered in the food and in their waste. By mid-March, at least 14 animal deaths and 14,000 cases of sickness were traced directly to this food poisoning. Many more could have occurred but were not reported. As a result, more than 60 million cans of animal food were recalled. The first question asked by investigators was how melamine, which was produced by processing of coal in China, wound up in pet food. As it turned out, industrial melamine scraps are added to many kinds of animal food in China largely as filler or a source of nitrogen. An overabundance of industrial melamine scraps in China resulted in the lowering of prices. The lower prices presented an opportunity for pet food companies to increase profits by using the melamine as filler. The second question is how such a normally relatively nontoxic substance as

melamine could have caused the acute health crisis that it did. The apparent answer is that melamine can react with cyanuric acid to form a salt called melamine cyanurate, which is apparently far more dangerous than either of the reactants. It is thought that this salt and the combination of melamine and other compounds may work synergistically to be far more dangerous to the health of the animals than the cumulative effects of the compounds by themselves. The public outcry and recall of the products caused tension between China and the United States. China turned away several cargo shipments of food from the United States in retaliation, claiming that they were tainted and unfit for human consumption.

**mercury** Mercury is an inorganic element that is designated as a heavy metal and a contaminant-pollutant of great concern, ranking number 3 on the 2007 Priority List of Hazardous substances. Although there are numerous natural sources of mercury, as well as mine spoils, that can be dangerous to extremely dangerous, it is the manufactured sources that are of greatest concern. There are good historic records of mercury toxicity in humans, especially among hatters, who were exposed to high levels through wool felt processing. The “Mad Hatter” in Lewis Carroll’s *Alice in Wonderland* has now become the most famous example, albeit fictional, of the effect of mercury on the nervous system. A more sobering example was provided by the large industrial emissions of mercury into the harbors of Japan near Minamata in the 1950s, causing widespread mercury poisoning in fishing villages. Even metropolitan areas were affected by this poisoning. There was another poisoning event in Iraq, when people began consuming processed grain intended for planting that had been treated with a methylmercury-based fungicide, a common practice. Although mercury is ever more tightly regulated and controlled

in the United States, for the foreseeable future, it remains a serious health threat. Mercury has been found in 714 of the first 1,467 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List), a very high percentage.

### PROPERTIES, USE, AND PRODUCTION

Mercury is a naturally occurring inorganic element that is present in rocks and soils throughout the Earth. Mercury occurs in three forms: metallic mercury; inorganic mercury, typically called mercury salts; and organic mercury, or organomercurials, and most commonly, methylmercury. Pure metallic mercury is the only liquid metal (and emitting mercury vapor) at room temperature, but many mercury compounds, both inorganic and organic, are solids. It is mined primarily as the mineral cinnabar and refined to usable form. There is no current mine production of mercury in the United States, but it is often imported. As much as 248 tons (225 metric tons) of mercury was imported in 2006, which continues a slight increasing trend since 2002, with the exception of 2003 and 2004, when only 50.6 and 55 tons (46 and 50 metric tons), respectively, was imported. Imports are primarily from Chile (30 percent), Peru (26 percent), Australia (20 percent), and Germany (12 percent). A big source of mercury, however, is reclamation and recycling of old products that contain mercury. In the past, mercury was used for mining, industrial applications, fungicides, batteries, paints, thermometers, barometers, mercury vapor and fluorescent lamps, medical equipment, and numerous medicines, computers, thermostats, switches, dental amalgam, and automobile convenience switches among other products. It is primar-

ily used in the United States for chlorine-caustic soda production, but also for batteries, cleansers, fireworks, pesticides, and skin creams and soaps.

### ENVIRONMENTAL RELEASE AND FATE

It is estimated that more than 150 tons (136 metric tons) of mercury is released into the environment each year from a variety of industrial sources. The single largest sources of environmental mercury are coal-fired electric power plants, producing nearly one-third of all mercury emissions in the United States, although some estimates of mercury emissions from these sources are much higher. The mercury is an impurity in the coal in very small amounts that is released into the atmosphere during burning. Through this widespread dispersion of mercury from the numerous coal-fired power plants burning increasing amounts of coal as the price of oil escalates, mercury contamination is becoming an even more serious problem. The situation is exacerbated because most U.S. power plants are exempt from the pollution controls of the Clean Air Act; in addition, mercury emissions are not specifically regulated. Formerly, when houses were heated with coal and coal-fired steam locomotives were the main source of transportation, coal emissions were a worse problem, although they were mainly confined to large cities.

The second largest sources of mercury emissions to the environment are incinerators, producing nearly 29 percent of total mercury emissions: Municipal waste incinerators produce about 18.7 percent of the emissions, and medical waste incinerators produce the remaining 10.1 percent. Items containing mercury are the source of this waste, although legislation is gradually reducing the amount of mercury found in common materials, and that reduction will in turn reduce mercury in the emissions. Incineration is regulated by the EPA. Coal-fired industrial, commercial, and residential boilers are the next greatest source of environmental mercury, producing about 17.9 percent of total emissions. Coal-fired residential boilers are rare in the United States but relatively common in some countries.

Industrial plants can also produce significant amounts of mercury. Chlorine production by plants that use the mercury cell process are the greatest single source, producing 4.5 percent. Dust emissions from cement plants also release mercury into the environment. Although the United States has significantly reduced or eliminated mercury content in common items such as thermometers and fluorescent lights, many other countries have not. Even in the United States, many automobile parts, appliances,

**Victim of mercury poisoning in Minamata, Japan, ca. April 1993—local seafood contaminated by industrial wastewater contained methylmercury compounds** (© Michael S. Yamashita/CORBIS)

and electronics, and some heavy equipment still contain mercury. Even some old sources of mercury persist in the modern environment. To separate gold ore from gangue minerals, the gold mining industry used vast quantities of mercury, most of which was dumped into streams and was deposited in the sediments. Even though the process was abandoned long ago, the mercury persists in the environment.

Mercury emissions fall out or are washed out of the atmosphere and deposit in soils, sediments, and bodies of water. Much of the deposited mercury can be washed into streams during precipitation events. Metallic and inorganic mercury are toxic even in small quantities. Even more hazardous is methylmercury, which is an industrial emission product or is formed in water, when certain bacteria convert mercury salts into it. Methylmercury is an extremely powerful neurotoxin that is very persistent in the environment. Methylmercury bioaccumulates in plankton and insects and works its way up the food chain to fish, amphibians, reptiles, birds, and mammals. The health effects to aquatic life include immune and endocrine damage to freshwater fish such as trout, perch, and pike. Loons in Canada and New England eat these fish and have been found also to have elevated methylmercury levels. They suffer behavioral and reproductive problems. Other species higher up the food chain, including ducks, mink, otters, raccoons and alligators, have shown the effects of methylmercury, as well. In one case an endangered Florida panther died of mercury poisoning. The most toxic form of mercury is dimethyl mercury, a single drop of which on the skin can kill a person.

Marine animals are also exposed to methylmercury. Sharks have been documented to contain high levels of methylmercury, as have common seafood species such as tuna and swordfish and gamefish such as king mackerel. The most publicity that mercury has gained as a threat is through its presence in tuna and swordfish. A national educational program has alerted Americans to the danger of eating too much of these fish species, making mercury one of the most well-known inorganic pollutants.

### HEALTH EFFECTS FROM EXPOSURE

Humans are at the top of the food chain and, as such, are highly susceptible to the biomagnification of methylmercury contamination. In high concentrations, it affects humans by outright poisoning, but its primary effect is its damage to the human central nervous system through its function as a potent neurotoxin. It has also been found to damage the cardiovascular system, the immune system,

and several other physiological systems to a lesser extent. In children, even low concentrations of mercury can damage the developing brain; the younger the child, the worse the effects. They can develop deficiencies in IQ, attention deficit problems, and motor function issues. Unborn children are even more prone to problems, and, as a result, expectant mothers must be very careful about their seafood intake. In 2005, the National Institutes of Health estimated that one woman in 12 in the United States has more mercury in her blood than is considered safe by the EPA. Consequently, between 300,000 and 600,000 children born each year could be at risk for adverse neurodevelopmental effects from exposure to mercury.

Acute exposure to high levels of metallic mercury vapor in the air can damage the lining of the mouth and irritate the lungs or cause nausea, vomiting, diarrhea, increases in blood pressure or heart rate, skin rashes, and eye irritation. Long-term exposure to mercury vapors and methyl mercury primarily damages the kidney and brain and causes personality changes, tremors, vision problems, hearing loss, loss of sensation and muscle coordination, and difficulties with memory. Long-term chronic exposure of laboratory animals to mercury salts and methylmercury produces kidney damage, elevated blood pressure and heart rate, stomach problems, immune system damage, nervous system damage, and damage to a developing fetus, potentially causing spontaneous abortion. Long-term exposure also results in an increase in tumors of various kinds; however, mercury is not regarded as a carcinogen at this time.

### REGULATIONS ON HUMAN EXPOSURE

In 1994, the EPA found mercury to be a hazardous pollutant that must be regulated under the Clean Air Act. The EPA and Food and Drug Administration (FDA) limit inorganic mercury to two parts per billion (ppb) parts of water in drinking water under the Safe Drinking Water Act. They further recommend that the level of inorganic mercury in rivers, lakes, and streams be no more than 144 parts mercury per trillion (ppt). The FDA has set a limit of one part per million (ppm) of methylmercury in seafood products and seeds sold through interstate commerce. The Occupational Safety and Health Administration (OSHA) has set a limit of 0.1 milligram of mercury per cubic meter of workplace air for organic mercury and 0.05 milligram per cubic meter for metallic mercury vapor during an eight-hour-workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) limits metallic

mercury vapor in workplace air to 0.05 milligram per cubic meter during a 10-hour-workday, 40-hour workweek.

In 2000, the EPA further decided that mercury from power plants is a risk to public health. Normally, they would have applied existing air-toxin regulations to the problem, which would have reduced power plant emissions by 90 percent within three to five years. Upon entering office, however, President George W. Bush ordered a reinvestigation of the issue. In 2005, a new regulation plan was announced using “cap and trade” market mechanisms that permit trade of pollution rights instead of mandating emission controls. The plan is designed to reduce mercury emissions by 70 percent by 2018, but the Congressional Research Service estimated that such a reduction under this program would not occur until at least 2030.

**methoxychlor** Dichlorodiphenyltrichloroethane (DDT) was the most widely used pesticide in the world until it was banned in the United States in 1972. To fill this great gap, there was a rush of other pesticides to the market to replace it. One of the more successful of these replacement pesticides has been methoxychlor, the production and use of which boomed during the 1970s and early 1980s. It even outlasted many of the other DDT replacements, which were subsequently banned during the 1980s and 1990s for similar negative ecological and public health effects. All pesticides, including methoxychlor, are designed to harm or kill organisms and, consequently, are not particularly friendly to the natural environment. In recent years, the use of methoxychlor has declined, as new advanced and less dangerous pesticides are developed. Methoxychlor is also known as Chemform Methoxychlor, Dianisyl methoxychlor, Dimethoxy-DT, DMDT, ENT 1716, Higalmetox, Marlato, Methoxide, Methoxychlor, Methoxy-DDT, NCI-00497, OMS-466, and Prentox. Methoxychlor has been ranked as the number 61 worst environmental threat of the 275 chemicals on the 2007 CERCLA Priority List of Hazardous Substances, and it has been found in 58 of the first 1,613 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List) where it was tested.

#### PROPERTIES, USE, AND PRODUCTION

Methoxychlor is a synthesized organic chlorinated hydrocarbon and classified as a diphenyl alkane insecticide. In its pure form, it is a colorless to pale yellow crystalline solid with a mild fruity or musty odor. It has been available in several forms, including technical grade concentrate, wettable powder, dust, granules, emulsifiable concentrate, and pressurized spray. It is primarily effective on houseflies, mosquitoes, cockroaches, chiggers, various field crop insects, and insects that infest stored grains. It is registered for use on 85 different crops including numerous fruits and vegetables, soybeans, nuts, and alfalfa, as well as forests and ornamental plants.

It has been used for insect control near barns and in greenhouses and for landscape maintenance and residences. It is also used to kill parasites on dairy and beef cattle, as well as pets.

Production of methoxychlor greatly increased in 1972 when DDT was banned. By the late 1970s and early 1980s, production peaked at more than 5 million pounds (2.3 million kg) but then decreased solidly through 1986, when usage was 500,000–900,000 pounds (227,272–409,090 kg) per year. In the early to mid-1990s, usage was down to 300,000–500,000 pounds (227,272–136,363 kg) annually, and it has never recovered.

### ENVIRONMENTAL RELEASE AND FATE

Compared with its predecessor, DDT, methoxychlor is much less dangerous to the environment by virtue of its generally lower toxicity and lower persistence. As are most other pesticides, it is foremost purposefully released to the environment as a non-point source pollutant, either sprayed onto crops and plants or applied to soil and seeds. Some is released into the air during spraying, but because it does not evaporate readily, very little vapor is released. The breakdown of vaporized methoxychlor is primarily through photolysis with a removal half-life estimated at one to 11 hours. The only way it can be widely distributed is by attaching itself to dust particles and being carried by the wind, either settling by gravity or being washed out by precipitation. It has even been detected in arctic snow, but its levels there are extremely low.

Upon its release into the soil, methoxychlor primarily binds tightly to particles in the top few inches of the surface, depending upon the chemistry and condition of the soil. Under aerobic conditions, it is quite persistent with a removal half-life of longer than 100 days through chemical reactions and biodegradation. In some instances, residues have been found up to 18 months after application to agricultural fields. Anaerobic biodegradation, by contrast, is much quicker, with a removal half-life of less than 30 days. The amount of methoxychlor leached into the groundwater is generally small; however, water from a number of wells in New Jersey has been found to have minor amounts of it. The metabolites of methoxychlor are equally dangerous and much more soluble.

Methoxychlor is not particularly soluble in water and is removed quickly by evaporation and chemical degradation. Melting snow and storm runoff, however, can wash away soil particles to which methoxychlor is adhered. These particles can be transported into surface waters and be carried in suspension.

Several rivers in the United States have been found to have very low levels of methoxychlor, including the Niagara River in New York and the James River in Virginia. The particles eventually settle into the sediment, where they are broken down with a removal half-life ranging from 37 to 46 days, depending upon chemistry, microorganisms, and physical conditions.

Methoxychlor has variable ecological effects. It is nontoxic to bees, slightly toxic to birds and mammals, but highly toxic to aquatic organisms and insects. It bioconcentrates moderately in aquatic organisms. Fish, depending upon the species, can concentrate it from 138 to 8,300 times ambient levels. Mussels, however, were found to have bioconcentration factors as high as 12,000 times ambient levels.

### HEALTH EFFECTS FROM EXPOSURE

In general, methoxychlor has been considered to be a good replacement for DDT for its health effects, as well as its effectiveness as an insecticide. The EPA has designated it as class IV in terms of its toxicity, indicating that it is only slightly toxic to humans. Most of its adverse health effects were observed in laboratory animals, rather than humans. Symptoms of acute exposure to methoxychlor include depression of the central nervous system in the form of headache, dizziness, and confusion, in addition to muscle weakness and diarrhea, followed by tremors, convulsions, periodic and continuous seizures, and, with increasing dosage, ultimately death within 36–48 hours by respiratory failure and brain paralysis. Symptoms of long-term chronic exposure at low doses in laboratory animals have included prostate, kidney, and liver damage; reduced weight; and death within 45 days, but more commonly numerous and severe reproductive effects. Decreased fertility of up to 100 percent was discovered in laboratory animals in some studies. Maturation of both male and female reproductive organs was found to be retarded and included accompanying hormonal effects. Genetic damage was permanent and, in some cases, was even passed on to subsequent generations. Birth weights of offspring were reduced, and skeletal deformities and lung problems were common.

Methoxychlor is not classified in terms of its human carcinogenicity by both the EPA and the International Agency for Research on Cancer. The general opinion of regulatory agencies is that it is not carcinogenic. There are, however, several studies that found increased incidence of cancer of the liver, testicles, ovaries, bones, and skin in a variety of laboratory animals. There was even a report of increased leukemia in humans. In contrast, there are

at least as many studies that found no connection of methoxychlor with cancer of any type. This apparent enigma has caused great controversy about the relative safety of methoxychlor.

### REGULATIONS ON HUMAN EXPOSURE

Federal agencies limit workers' and the general public's exposure to methoxychlor because of these health effects. The EPA set the limit of methoxychlor in drinking water at 40 parts per billion (ppb) under the Safe Drinking Water Act, and the Food and Drug Administration limits bottled water to the same levels. The Occupational Safety and Health Administration (OSHA) set a limit of 15 parts per million (ppm) of methoxychlor in workplace air (PEL) during an eight-hour-workday, 40-hour workweek. The National Institute of Occupational Safety and Health (NIOSH) set the immediately dangerous to life and health (IDLH) concentration at 5,000 ppm. The EPA also limits the amount of methoxychlor in some agricultural products. In 1995, California banned the use of methoxychlor.

**methylene chloride** Methylene chloride, also known as dichloromethane, is an organic compound that was widely used in both industrial and consumer applications until health concerns curtailed much of its use. One of its more notable uses was in hairspray, where human exposure to it is very high as a result of its method of application and its widespread use. It was found to be at dangerous levels in the ambient air of many beauty salons, spurring part of the regulatory action to limit its use. Methylene chloride has been designated the 80th worst environmental threat of the 275 compounds on the 2007 CERCLA Priority List of Hazardous Substances. It has been found in 882 of the first 1,569 U.S. Environmental Protection Agency (EPA)–designated Superfund sites (National Priorities List), a very high percentage. It is the physical and chemical characteristics of the chemical that make it so dangerous to public health.

### PROPERTIES, USES, AND PRODUCTION

Methylene chloride is a synthesized organic chlorinated hydrocarbon in the family of saturated aliphatic halogenated compounds. It occurs as a colorless volatile liquid with a sweet odor similar to chloroform. Methylene chloride is used in a variety of applications including its main use in paint removers (30 percent); in formulated products (24 percent) such as adhesive (especially for furniture), solvent, spray paint, and lubricant; in chemical processing (18 percent) for thermoplastics, photographic film, plastic molding, and as an extraction agent for pharmaceuticals and vitamins and a coating; in the manufacture of soft polyurethane foam (15 percent); and as a metal cleaner and degreaser (4 percent). The remaining 9 percent is found in a variety of applications including an extraction agent for spices, oils, fats, waxes, and caffeine in coffee and tea. It is also used in many consumer items such as spray shoe polish, water repellent, spot remover, wood floor cleaners, contact cement, super glue, spray adhesive, adhesive remover, silicone lubricant, electronic cleaner for televisions and videocassette recorders, wood stains, varnishes and finishes, paint thinner, paint remover, aerosol spray paint, aerosol rust remover, outdoor water repellent, trans-

mission cleaner, battery terminal protector, brake cleaner, and gasket remover. Previously, one of its many applications was as an insecticidal fumigant for strawberries, citrus, and various grains.

Methylene chloride was first synthesized in 1840 but not widely available until the 1940s, when it was introduced as a less flammable solvent than the currently used solvent at the time. Its production and use have varied over the years, increasing by an average of 3 percent between 1970 and 1983 before decreasing by 1–2 percent through 1990. The decrease began when it was suspected to be a carcinogen, and bans in such products as hairspray (banned in 1989 by the Food and Drug Administration) were imposed. The domestic production in 1994 was 403 million pounds (183 million kg) but declined to about 300 million pounds (136 million kg) by 2000.

### ENVIRONMENTAL RELEASE AND FATE

Methylene chloride enters the environment mainly as a point source pollutant from industrial release, spills, and leaks during transport and storage or from improper disposal. It is primarily released into the air through evaporation and less commonly into water and soil. The breakdown chemical reaction is 90 percent to carbon dioxide, which is not dangerous. In air, methylene chloride is broken down by photolysis and reaction with photochemically produced hydroxyl radicals. The removal half-life from air ranges from 53 to 127 days, depending upon temperature, air chemistry, and sunlight. Much of the methylene chloride that is released into the water evaporates into the air. That which remains in water does not dissolve easily, and, as a result, only small amounts are found in surface water, except around waste sites. The removal half-life from water is one to six days, depending upon temperature, chemistry, and bacteria present. In soil, methylene chloride also mainly evaporates or attaches loosely to the soil particles. Some leaching occurs, as it has been found at a few locations in well water in very small concentrations. Otherwise, it is broken down by microbial action.

### HEALTH EFFECTS FROM EXPOSURE

Both acute and chronic exposure to methylene chloride produces adverse health effects. Inhalation of methylene chloride results in increased carbon monoxide and consequent reduction of oxygen in the blood. Acute exposure results in temporary impairment of hearing and vision, fatigue, drowsiness, and irritability, followed by slowed reaction times, and,

with increasing dosage, reduced hand-eye coordination. High doses can lead to unconsciousness, narcosis, and ultimately death. Chronic exposure, like that experienced by workers, results in damage to the central nervous system, marked by headaches, dizziness, nausea, loss of memory, paresthesia, tingling sensation in the hands and feet, and fainting, as well as possible liver damage. When pregnant laboratory animals were exposed to methylene chloride, an increase in spontaneous abortions, decreased birth weights, and some developmental problems in offspring resulted.

Methylene chloride has been documented in laboratory animals to produce an increased incidence of cancer of the liver, lungs, and salivary glands, and benign mammary gland tumors. It was for this reason that the EPA classified methylene chloride in group B2, as a probable human carcinogen. Additionally, methylene chloride has been labeled as reasonably anticipated to be cancer causing by the Department of Health and Human Services and a possible human carcinogen by the World Health Organization and International Association for Research on Cancer (group 2B).

### REGULATIONS ON HUMAN EXPOSURE

As a result of the danger to public health, federal agencies limit workers' and the general public's exposure to methylene chloride. The EPA set the limit of methylene chloride in drinking water at five parts per billion (ppb) under the Safe Drinking Water Act. They also require that any environmental release of 1,000 pounds (454 kg) or more be reported to the National Response Center. The Occupational Safety and Health Administration (OSHA) has set a limit of 25 parts per million (ppm) of methylene chloride in workplace air (PEL) during an eight-hour-workday, 40-hour workweek and a short-term exposure limit (125 ppm). The National Institute of Occupational Safety and Health (NIOSH) limits methylene chloride in workplace air to 75 ppm during a 10-hour-workday, 40-hour workweek in the presence of carbon monoxide at concentrations of 9.9 ppm or more. They further set the immediately dangerous to life and health (IDLH) concentration at 2,300 ppm. The National Occupational Hazard Survey conducted by NIOSH in 1972–74 estimated that more than 2.5 million workers were exposed to methylene chloride. In 1987, the EPA estimated exposure of more than 1 million workers.

**methyl parathion** Methyl parathion is another of the organochloride insecticides that have been reported in the news because of the many health problems it has caused. It is especially well known for poisoning incidents from improper handling in developing countries, especially in Central and South America. There were 1,243 reported poisoning incidents involving methyl parathion in 1982–91 in Oarana State, Brazil, alone. The United States, however, has not completely escaped poisoning incidents by methyl parathion. There were several criminally negligent incidents in the mid-1990s in Ohio, Mississippi, and Louisiana that received media attention. The cases in Mississippi and Ohio in particular involved the spraying of 1,500 homes and businesses with methyl parathion by unlicensed operators. As a result, more than 4,000 people had to be relocated in temporary accommodations, and cleanup costs totaled around \$50 million. The offender in Mississippi faced a maximum of 21 years in prison and/or up to \$2.1 million in fines for the offenses but received a lesser sentence and fine. The offender in Ohio faced up to six years in prison and/or a fine of up to \$350,000 and also received a lesser sentence.

Since 1978, methyl parathion has been designated as a restricted use pesticide (RUP) by the U.S. Environmental Protection Agency (EPA) as the result of its toxicity. It is also known by several trade names including Bladan M, Cekumethion, Dalf, Dimethyl Parathion, Devithion, E 601, Folidol-M, Fosferno M50, Gearphos, Kilex Parathion, Metacide, Metaphos, Metron, Nitrox 80, Partron M, Penncap-M, and Tekwaisa. As with most pesticides, it is not a common pollutant in EPA-designated Superfund sites (National Priorities List) and has been identified

in 16 of the first 1,585 sites. Nevertheless, because of its toxicity, methyl parathion has been ranked the 264th most dangerous pollutant on the 2007 CERCLA Priority List of Hazardous Substances.

**PROPERTIES, USES, AND PRODUCTION**

Methyl parathion is an organophosphate pesticide and an organic pollutant that is synthetically produced and does not occur in nature. Methyl parathion is a nonsystemic pesticide that has two forms—a pure form of white crystals and an 80 percent technical-grade solution. It is primarily available as an emulsifiable concentrate formulation and applied as a spray. It is used to control chewing and sucking insects primarily in cotton and field crops but also in a wide range of crops, including cereals such as wheat, rice, corn, and barley; and in soybeans, various types of fruits and vegetables, vines, and ornamental plants. Methyl parathion was originally developed by the German pesticide company Bayer and introduced onto the market in the early 1950s. It has been used in the United States since 1952, although it was not registered for use until 1954.

**ENVIRONMENTAL RELEASE AND FATE**

As with most pesticides, methyl parathion is primarily released as a nonpoint source pollutant that is sprayed over a large area to soil. The act of spraying releases it to the air, polluting it, and drifting spray can affect surface water, as well, as it undergoes fallout or washout in precipitation. If released to soil, methyl parathion sticks to the clay and organic particles and then is rapidly degraded by bacteria. It has a low persistence in the soil environment, with reported field removal half-lives of one to 30 days, though some laboratory studies suggest a persistence of 10 days to two months. In contrast, if large concentrations of methyl parathion are applied to soil, as in an accidental spill, complete degradation occurs only after many years. This is because it kills the soil bacteria at high concentration. It generally does not leach through the ground and enter the groundwater.

If released to water, methyl parathion breaks down quickly by the action of the water, bacteria in the water, and sunlight. It degrades very rapidly in seawater and in lake and river waters, with complete degradation occurring within two weeks to one month. The rate of degradation increases as a function of temperature and exposure to sunlight. Some laboratory studies, however, have found a much greater persistence with an estimated removal half-

life in aqueous solution of 175 days. In air, methyl parathion is broken down quickly by sunlight.

Methyl parathion is considered highly toxic to aquatic invertebrates and birds, toxic to bees, and moderately toxic to fish, cattle, and wild animals. Major bird kills, especially from improper use in Central America, have been attributed to it.

According to the EPA Toxics Release Inventory (TRI), industrial releases of methyl parathion to the environment were 1,442 pounds (655 kg) in 1995, 1 pound (0.45 kg) in 2000, and 501 pounds (228 kg) in 2006. It is not a particularly common compound in industrial applications.

### HEALTH EFFECTS FROM EXPOSURE

The reason that methyl parathion is restricted or banned completely is the number of adverse health effects it produces from exposure. For a short-term acute exposure, the first adverse effects are a bloody or runny nose, coughing, chest discomfort, and difficulty in breathing. Skin contact commonly results in sweating and involuntary muscle contractions. After exposure of any type, other systemic effects typically begin within a few minutes but may be delayed for up to 12 hours. These symptoms include nausea, vomiting, diarrhea, abdominal cramps, headache, dizziness, eye pain, blurred vision, constriction or dilation of the pupils, tearing, salivation, sweating, and general confusion. At higher doses, poisoning affects the central nervous system and produces slurred speech, loss of coordination and reflexes, weakness, fatigue, and eventual paralysis of the body extremities and respiratory muscles. Death is generally caused by respiratory failure or cardiac arrest.

For long-term chronic exposure to methyl parathion, symptoms include impaired memory and concentration, disorientation, severe depression, irritability, confusion, headache, speech difficulties, delayed reaction times, nightmares, sleepwalking, drowsiness, and insomnia. Some studies of long-term exposure of laboratory animals to methyl parathion have shown significant depression of red blood cells and plasma cholinesterase. Studies on pregnant mice showed reduced weanling survival and birth weight and suppression of fetal growth and bone formation in the offspring that survived.

### REGULATIONS ON HUMAN EXPOSURE

As a result of the many adverse health effects from exposure to methyl parathion as well as the threat to the environment, federal agencies have imposed

a variety of regulations on its usage and exposure. In addition to listing it as a restricted use pesticide (RUP), the EPA decided to cancel the registrations of emulsifiable concentrate formulations as of April 30, 1997. Further, as of December 31, 1999, methyl parathion is no longer permitted for use on foods that are commonly consumed by children such as apples, peaches, pears, carrots, peas, grapes, nectarines, cherries, tomatoes, broccoli, cauliflower, lettuce, and spinach, among many others. It was also canceled for many nonfood uses such as ornamental plants and nursery stock. Although there are no regulations under the Safe Drinking Water Act, the EPA recommends a maximal exposure of 0.3 mg per liter for 1 to 10 days for children, 0.03 mg per liter for longer-term exposure for children, and 0.002 mg per liter for lifetime exposure of adults. The National Institute of Occupational Safety and Health (NIOSH) recommends a maximal exposure in the workplace of 0.2 mg per cubic meter of methyl parathion in air for a 10-hour-workday, 40-hour workweek. Methyl parathion has been banned from usage in Indonesia, Sri Lanka, and Tanzania, and it is severely restricted in Colombia, Korea, China, and Japan.

**Meuse Valley disaster Belgium (December 1–5, 1930) Air Pollution** One of the most dramatic examples of the effects of exposure to excessive levels of air pollution on human health occurred in early December 1930 in the Meuse Valley, Belgium. This valley has experienced numerous incidents of tragedy and hardship. The navigable waters of the Meuse River, combined with plentiful deposits of valuable coal, have made its 15-mile (24.1-km-) long course one of the most important industrial regions of Europe. This economic importance, combined with the strategic location between France and Belgium, have made the valley a battleground numerous times since the 13th century. More recently, the movement of German troops toward the Meuse River in the closing days of World War II played a key role in the Battle of the Bulge, which took place nearby.

### BACKGROUND

In 1930, the Meuse Valley was home to coke ovens, blast furnaces, zinc smelters, fertilizer factories, and sulfuric acid plants. These companies provided the region with thousands of high-paying jobs and helped support a thriving national economy in Belgium. The 9,000 residents not only worked on small farms and in villages raising crops and livestock, but also were steelworkers, glassblowers, and munitions manufacturers. The 12-mile (19.3-km) part of the valley between the towns of Liège and Huy was the most developed, but also the narrowest, bordered on both sides by cliffs rising 270–350 feet (82.3–106.7 m) above the valley floor.

This restricted geography caused in the Meuse Valley to be plagued with almost constant air pollution. At the time, most people considered pollution an unavoidable consequence of industrial prosperity, and little pressure was placed on local industries to reduce emissions or even consider the impacts of releasing enormous quantities of particulate, sulfur dioxides, and other noxious gases into the air. The residents of the Meuse Valley were accustomed to some of these consequences. In 1911, many cattle reportedly died as a result of air pollution, and in the central valley town of Engis, windowpanes and light bulbs were etched or frosted by an airborne release of hydrofluoric acid.

### THE AIR POLLUTION DISASTER

Between Monday, December 1, and Friday, December 5, 1930, a winter temperature inversion resulted in an industrial disaster that, for the first time, focused modern scientific and medical attention on

the public health impacts of air pollution. It was a cool evening in the Meuse Valley, with temperatures just above freezing, a weak easterly wind (less than two miles per hour [3.2 km/h]), and relatively high barometric pressures. Above the valley walls, however, a warm front was carrying in a dense, humid air mass that formed a thermal blanket over the Meuse Valley, resulting in a thick fog and greatly reducing the movement or dispersion of polluted air out of the valley. During this time, factory operations were on the usual weekday schedule, and the industrial stacks and chimneys continued to exhaust pollutants into the now-stagnant atmosphere.

The first signs of a problem began on December 3, when hundreds of people almost simultaneously throughout the entire valley began to experience respiratory problems. The most common symptoms included laryngeal irritation, uncontrollable coughing, chest pain, and difficulty in breathing. More severe cases included cyanosis, asthmatic breathing, nausea and vomiting, and even pulmonary edema. Sixty people died on December 4 and 5, and the total deaths for the entire event were 63. Of these, 56 were in the eastern half of the valley, and only seven were west of the midvalley village of Engis. The mortality rate over the period was 10.5 times normal. The elderly were at most risk; the average age of those who died was 62. Children and people who had other complicating medical conditions, such as cardiac or respiratory disease, also were disproportionately affected. By December 5, weather conditions changed, and the fog began to dissipate, fresh air began to make its way into the valley, and the immediate public health crisis passed. Autopsies of 15 of the dead showed excessive amounts of soot in the lungs.

### THE AFTERMATH

The Belgium government commissioned a panel of experts to study and determine the reasons for the disaster. The panel included experts in meteorology, toxicology, forensic science, and chemistry. They reviewed and evaluated a wide variety of factors that could have contributed to the catastrophe. These potential factors ranged from a viral epidemic introduced by the cold weather, to the secret testing of wartime chemical gases to toxic sand blown in from the Sahara. After a year of study, investigators found that the deaths and other related medical complaints were due to a local irritant present in the outside air. This irritant was a concentration of sulfur dioxide (SO<sub>2</sub>) in the air in the range of 100 mg/m<sup>3</sup>. Safe levels of SO<sub>2</sub> exposure are in the 20–30 mg/m<sup>3</sup> range.

Some of this SO<sub>2</sub> reacted with water vapor to form dangerously high levels of sulfuric acid in the air.

The SO<sub>2</sub> was produced by the domestic and industrial burning of coal in the valley, which was concentrated in the ambient air by the combination of a temperature inversion and the natural geography of the Meuse Valley. Up to 130,000 pounds (59 metric tons) per day of SO<sub>2</sub> was estimated to have been produced in the Meuse Valley through the burning of coal. The government's report also indicated that some of the other industrial pollutants present in the atmosphere, particularly zinc and iron from metal smelters, probably increased the amount of sulfuric acid production. Another contributing factor was the absorption of the SO<sub>2</sub> onto very small particles of soot, which were able to work their way deep into the lungs and bronchial passages.

As an air pollution event, the Meuse Valley catastrophe had public health consequences that reverberated across Europe. It was the first time that nonoccupational exposure to air pollution was directly connected to the deaths of people living near the factories and mills where the SO<sub>2</sub>, hydrofluoric acid, and other toxic contaminants were being released. The panel of experts retained by the Belgium government did an excellent job of scientifically dismissing nonindustrial sources of the pollution such as damp moist air in the fog, causing flu or some other sort of viral epidemic. A subsequent commission, also formed by the Belgium government, recommended that a central authority assume responsibility for the issuance of permits to discharge pollutants into the air. This central commission would be less susceptible to local political pressures and would have the ability to monitor air quality in the vicinity of the plants it had permitted. Little was done, however, to implement these recommendations. Air pollution, however, was now on the agenda of the scientific community, and the days of freely discharging contaminants into the atmosphere were coming to an end.

One group of public health officials who closely followed the events in the Meuse Valley were those in Great Britain. For years, cities such as London and Glasgow had suffered through notorious "pea soup" fogs caused by a combination of extensive coal burning and the influx of cool, damp air from the North Sea. London's geography had prevented these fogs from lingering, but officials were concerned that, given the right set of meteorological conditions, a Meuse Valley-like disaster could occur. In 1952, it did, the London Killer Fog.

## Milan Army Ammunition Plant Milan, Tennessee (1987–present) Soil and Water Pollution

In 1941, the Department of Defense began construction of a munitions facility about 100 miles (160.9 km) northeast of Memphis, Tennessee, and just a few miles east of the small town of Milan. As World War II approached, the pace of construction quickened, and in January 1942, the new facility opened. By the end of the war, the Milan Army Ammunition Plant (Milan AAP) employed 10,000 people, who operated 14 process lines and were responsible for the loading, assembly, storage, testing, packaging, and shipment of demolition charges, mortar rounds, artillery projectiles, grenades, and various types of small arms ammunition. It was shut for a short time at the end of World War II but reopened during the Korean conflict and has remained operational ever since. Currently, Milan AAP has about 500 employees and is made up of 1,400 buildings and six active production lines on more than 22,000 acres (8,903 ha) of land. Production lines, along with administrative, maintenance, and other support activities, are contained within about 500 acres (202.3 ha). The remaining land area is needed to allow for safe (buffer) distances between local residents and explosive and munitions storage and testing areas.

The manufacturing, processing, and demilitarization or destruction of explosives require large amounts of water, both in formulating the compounds and in cleaning and washing vessels, piping, and other equipment. Currently, this wastewater is treated extensively to remove chemical and explosive residues before being discharged to a surface water body under permit conditions established by

## HEALTH EFFECTS FROM EXPOSURE TO RESIDUES OF EXPLOSIVES

Pollutant	Health Effects
RDX (1,3,5-trinitro-1,3,5-triazine)	Exposure (inhalation or ingestion) to large amounts can cause seizures. Long-term, low-level exposure effects on the nervous system have not been studied, although nausea and vomiting have been documented. EPA has classified RDX as a possible human carcinogen.
TNT (2,4,6-trinitrotoluene)	Workers exposed to high concentrations of TNT developed anemia and abnormal liver function. Long-term exposure led to severe skin irritation and cataracts. Animals involved in laboratory studies also developed blood and liver effects, including spleen enlargement and immune system damage. EPA has designated TNT as a possible human carcinogen.
HMX (Octogen or cyclotetramethylene-tetranitramine)	Little information on the adverse health effects of HMX is available. Animal studies suggest that exposure to HMX may harm the liver and central nervous system. EPA has not yet classified HMX as to its potential human carcinogenicity.
Tetryl (2,4,6-trinitrophenyl- <i>n</i> -methyl-nitramine)	Tetryl is no longer made or used but was a common World War II-era explosive. Workers handling Tetryl developed coughs, headaches, eye irritation, nosebleeds, and nausea. Their skin also became stained with a distinctive yellow color. Animal studies indicate that Tetryl damages the kidney, liver, and spleen. The EPA has not reviewed Tetryl to identify its potential to cause cancer in humans.

either the U.S. Environmental Protection Agency or the Tennessee Department of Environmental Conservation.

## POLLUTION OF THE SITE

Historical wastewater treatment processes at Milan AAP were not as efficient as the carbon-based filtering systems being used today throughout this facility's seven individual wastewater treatment plants. As a result, various explosives residues including TNT, RDX, HMX, and Tetryl contaminated soil, stream sediment, and groundwater. The primary sources of this contamination were wastewater and wash water that was released into open-topped and unlined drainage ditches and swales that led to sumps or surface impoundments and eventually emptied into intermittent and perennial surface water bodies adjacent to and flowing past the property. In particular, condensed liquids from the "O" Line operation, where high-pressure steam was used to flush TNT and TNT-RDX mixtures from munitions, was discharged into 11 unlined settling ponds, each with a 5.5-million-gallon (20.8-million-L) capacity. Sediment was periodically dredged from these ponds and stored on the ground to dry. Run-off and leachate from this sediment discharged into nearby drainage ditches, and liquid from the ponds flowed directly into surface water bodies.

Milan AAP's wastewater, like wastewater from many munitions facilities, is primarily made up of

"pink water," which is wash water associated with load, assemble, and pack (LAP) operations or with the demilitarization of munitions that have had contact with finished explosives. Pink water is actually clear and only turns pink or reddish or black, depending upon its final chemical composition, if exposed to light. The main ingredients of pink water are trinitrotoluene (TNT), which has a more characteristic red color (wastewater from TNT processing is sometimes called "red water"), and RDX. These types of explosives residues enter wastewater streams during equipment washing and during chemical neutralization of old munitions.

TNT and RDX residues are very resistant to biodegradation, volatilization, hydrolysis, and other natural transformation or breakdown processes because of their chemical composition. Once discharged into the environment, they tend to persist in soil and water. TNT is the least soluble of the high explosives, and it tends to remain present in the soil much longer than RDX and HMX. They are much more soluble and represent a significant threat to groundwater quality. Heavy metals including lead, arsenic, bismuth, copper, and others used in LAP operations are common cocontaminants at munitions facilities and can also contribute to soil and groundwater contamination.

Milan AAP's groundwater contamination occurs as a plume approximately 3,000–4,000 feet (914.4–1,219 m) long by 1,000 feet (304.8 m) wide and 140 feet (42.7 m) below the surface that has flowed

from the property and into drinking water supply wells. In addition, this groundwater contamination threatens the Memphis Sand Aquifer, which is a major source of potable groundwater for 10,000 people living in and around the city of Milan. As a result of this threat to public health, as well as other serious environmental conditions present on the site, Milan AAP was placed on the National Priorities List (NPL) as a Superfund site in July 1987, and an interagency agreement between the U.S. Environmental Protection Agency (EPA) and the Department of Defense was signed in 1989 committing both parties to conducting and managing an effective cleanup of the facility.

### THE CLEANUP OPERATIONS

One of the first steps in the remediation efforts was to control the off-site migration of contaminated groundwater. The army installed a series of pump-and-treat groundwater recovery systems that established a hydraulic barrier around the areas of the Milan AAP where contaminants are present in the groundwater. Water captured by a series of extraction wells is pumped to a treatment system where explosive residues (primarily RDX) are removed to levels below regulatory concern. Although there were some initial difficulties in making the pump-and-treat systems operational, the facility worked through these problems, and they currently are effectively preventing the movement of contaminated groundwater from the site. Approximately 85–90 percent of the contaminant plume is being captured, and modifications to the pump-and-treat system are being considered and will probably be implemented, depending upon ongoing performance.

The army also provided funds to the city of Milan to relocate and reinstall its drinking water well field. A Restoration Advisory Board (RAB) was established so that local residents; representatives of the army, EPA, the state regulatory agency; and other stakeholders can work together to develop an acceptable remedial plan for the Milan AAP.

To address soil issues, the O-Line ponds were capped so that soil and sediment in them could no longer leach metals or explosive residues into the groundwater. Other areas of contaminated soil are being excavated and treated on-site in a unique manner. In perhaps the largest test of phytodegradation, the U.S. Army Environmental Center, in cooperation with the EPA and the Tennessee Valley Authority, constructed two 2,400-square-foot (223-m<sup>2</sup>) gravel-bed wetlands. Four different types of grasses were planted in each wetland, and water containing high influent concentrations of TNT (4,000 parts per bil-

lion [ppb]), RDX, and HMX (averaging 9,000 ppb) was slowly discharged into each wetland cell. The goal was to reduce the concentrations of TNT to 2 ppb and of other compounds to less than 50 ppb. Except during a few winter months, these goals were achieved with more than 6.5 million gallons (24 million L) of explosive-contaminated water successfully treated by the system. The treatment cost using the constructed wetlands was approximately \$1.80 per 1,000 gallons (\$0.48 per 1,000 L) compared to cost of traditional treatment methods of almost \$4.00 per 1,000 gallons (\$1.06 per 1,000 L). The use of both phytodegradation and other bioremediation technologies is being expanded at Milan AAP to address both soil and sediment contamination.

Milan AAP is one of five specialty LAP munitions facilities around the country. The others—Iowa AAP, Kansas AAP, Lone Star AAP (Texas), and Lake City AAP (Missouri)—also have environmental problems, to one degree or the other, similar to the concerns at Milan AAP. The munitions produced by these plants have helped the United States defend itself for almost 70 years, and the Department of Defense, with some prodding by EPA as well as state and local stakeholders, is committed to their remediation and continued environmentally compliant operation.

### **military facilities and the environment**

Just as waging war has environmental consequences, so does preparing for war. The thousands of current and former military bases, storage depots, and weapons research facilities strategically placed across the United States and in other countries often are the sites of some of the most egregious environmental conditions yet discovered. The reasons for this are rooted not in an evil disregard for nature or an overwhelming sense of elitism, but rather in a single-minded dedication or focus on a very important mission: the defense of the United States. As Lyndon B. Johnson, 36th president of the United States, once said: “We don’t propose to sit here in our rocking chair with our hands folded and let the Communists set up any government in the Western Hemisphere.”

The location and development of military facilities, especially those built during and after World War II, were based on a variety of logistical and strategic factors such as distance from attack-vulnerable coastlines, availability of a reliable freshwater supply, access to transportation infrastructure and power, and location relative to population centers. In the 1940s, many of these bases and facilities were established when America was fighting for its very existence and the outcome was far from certain. Later, trying for 30 years simultaneously to prevent and to prepare for the threat of thermonuclear Armageddon only slightly moderated the military’s need to maintain an urgent, almost wartime attitude.

Considering the dire reason for military facilities, in choosing a site for a military base or nuclear weapons complex, the ways that bases or support facilities might adversely affect the local environment were not given much, if any, consideration. Rather, logisticians and government contractors were, by necessity and cultural predilection, single-mindedly focused on quickly and cost-effectively placing the base, depot, or research facility into operation.

Another factor that contributed to the environmental degradation is the nature of the materials used in the missions. The development, manufacture, storage, and maintenance of conventional and nuclear weapons involve the use of dangerous and hazardous chemicals. Many of the bases and facilities are large (often thousands of acres), to allow for privacy and security, rapid expansion, multiple uses, and processing and storage of large amounts of chemicals. This increases the risk of an uncontrolled release and can make it difficult to track and manage the environmental status of these materials. The veil of secrecy that hung over many of these installations also did not encourage environmental accountability.

The environmental impacts of military operations can be broadly classified into those associated with fuel storage and usage, equipment maintenance, development and testing of munitions, and land use.

### **FUEL USAGE AND STORAGE**

All the combined parts of the federal government, including the military, consume approximately 2 percent of the U.S. liquid fuel budget (oil, kerosene, gasoline, etc.), or roughly 440,000 barrels (19,987,000 L) per day. The military uses about 97 percent of this, which is more oil than any other governmental or private sector organization and more than many countries. About \$20 billion was spent by the military on oil in 2007. The U.S. Air Force is the single biggest oil consumer, using just more than 50 percent. The U.S. Navy and U.S. Marine Corps use 32 percent of the oil, and the U.S. Army uses 12 percent. “Mobility”-type fuel for aircraft, ships, and vehicles makes up about 75 percent of total consumption, with jet fuel accounting for almost 69 percent of mobility fuel.

Much of the rationale behind the creation of the U.S. Department of Energy’s Strategic Petroleum Reserve (SPR) was to ensure an adequate supply of fuel for the military in times of crisis or interruption of foreign supplies. The SPR is a collection of four artificially created caverns carved out of salt domes in Louisiana and Texas on the Gulf Coast. Its total capacity is about 700 million barrels (111,291 million L). The crude oil stored in these immense caverns thousands of feet below the surface has been used to help lower heating oil costs for U.S. consumers in times of shortage and been sold to allies in the Middle East when their supplies have been disrupted by war or political turmoil.

The use and storage of these enormous amounts of gasoline, jet fuel, marine diesel, and other liquid fuels have resulted in significant environmental impacts. Liquid fuels are stored in aboveground and underground tanks that occasionally leak, are punctured or otherwise damaged, and discharge their contents into the soil and groundwater. At many military airports, fuel is dispensed through a buried high-pressure hydrant system from a central tank farm. By simply connecting a fuel line to a dispenser, aircraft can be refueled much more quickly and supply tankers reloaded without the need for transfer from limited-capacity tanker trucks. Even a pinhole leak in the subsurface lines of a hydrant system can discharge gasoline or jet fuel into the environment.

Effects of fuel usage and storage are exemplified at the U.S. Navy’s base on Diego Garcia, an island reef, about 6,700 acres (2,711 ha), in the Indian

**Fuel storage tanks at U.S. Navy base on Diego Garcia in the Indian Ocean, midway between Africa and Indonesia** (© Reuters/CORBIS)

Ocean some 1,000 miles (1,609 km) south of India. For most of its recorded history, Diego Garcia was a quiet plantation island, producing copra nuts used to make a fine oil for lighting and machining. In the early 1970s, the navy built a small communications facility on the island, and, as the Persian Gulf countries (especially Iran in 1979) started to become more critical to U.S. strategic and economic interests, military facilities on Diego Garcia were rapidly expanded. By the time of the first Gulf War in 1991, the island was home to about 1,700 military personnel and 1,500 civilian contractors as well as a modern operating airfield.

As part of the development of the island, a hydrant refueling system was constructed to support combat and other aircraft operations. Hydrant fueling systems are made up of fuel storage in aboveground or underground tanks, distribution lines that are usually underground pipelines, fuel dispensing hydrants near aircraft-parking spots, and pumps for moving fuel from the storage containers through the pipelines to the hydrants and into the aircraft. Hydrant systems can supply fuel to four or more aircraft simultaneously, transfer-

ring fuel at rates of up to several hundred gallons per minute.

At Diego Garcia, the 18-inch- (45.7-cm-) diameter buried pipeline connecting the hydrant fuel system to its supply tanks cracked and released at least 160,000 gallons (605,666 L) of jet fuel into the subsurface before the leak was detected and repaired. The released fuel was under a concrete airport tarmac and covered approximately nine acres (3.6 ha). To recover the fuel without interfering with airfield operations, the U.S. Air Force installed an in situ bioslurping system in a grassy area near the airstrip. This system included a vacuum pump and more than 1,000 feet (0.3 km) of horizontal polyvinyl chloride (PVC) piping connected to six recovery wells. Recovery tubes were placed about one foot (30.5 cm) into the water/fuel interface zone. A vacuum pump ran continuously in each of the recovery wells. In the first month of operation, 2,000 gallons (7,571 L) of fuel was recovered and capture rates over 18 months were about 1,000 gallons (3,785 L) of fuel per month. Given the success of this system, it was expanded to a 50-well system and used at an aircraft ramp area and eventually employed to remediate the

entire nine-acre (3.6-ha) plume. More than 100,000 gallons (378,541 L) of fuel has been recovered by the bioslurping system.

Between 1985 and 2006, the U.S. military total energy consumption decreased by 60 percent, with most of that reduction resulting from increasing energy efficiency of buildings and facilities. This reflects a trend observed since 1985, when the U.S. military consumed almost 180 million barrels (490,000 barrels per day, or 77.9 million L). In 2006, its oil consumption was down to 117 million barrels (320,000 barrels per day or 50.9 million L), in spite of supporting fuel-intensive missions in Iraq and Afghanistan.

### **EQUIPMENT MAINTENANCE**

Since the 1940s, the U.S. Navy has operated and maintained a fleet of more than 87,000 surface vessels, submarines, support ships (tugs and tenders), and near-shore patrol vessels. Over that same time, the U.S. Air Force has deployed more than 100,000 aircraft. By 2007, there were approximately 1.4 million people on active military duty, with another 1.5 million on reserve status, each needing specialized equipment (weapons, trucks, electronics, etc.). The enormous size and worldwide presence of the U.S. military, often in hostile environments, require that its equipment be tested and maintained to exacting performance standards. As an indication of how important this is, in 2007 the U.S. Army spent almost \$40 billion of its \$140-billion budget on equipment operation and maintenance (O&M) programs.

Equipment maintenance, especially at bases in operation before today's heightened awareness of soil and groundwater contamination, can have serious environmental consequences. Most military-related O&M programs can be classified into three types. User, or direct, support activities include inspection, cleaning, lubrication, and minor adjustments performed by the equipment operator. When necessary, direct support maintenance is carried out by specialized teams in fixed or mobile maintenance facilities. Intermediate, or general, support is performed by unit maintenance personnel and involves recovery, evacuation, inspection, troubleshooting, and some replacement of parts and assemblies as well as maintenance involving the repair of equipment. This type of maintenance generally is performed by specialized units in fixed centers, each of which specializes in a particular type of equipment (e.g., combat vehicles or missiles). Full maintenance also is carried out by highly specialized maintenance personnel in fixed facilities. It involves the rebuilding of entire items

and renovation of major assemblies (such as motors or transmissions) for return to general stocks.

The environmental consequence of maintenance activities, especially when vehicles such as ships, aircraft, trucks, and other vehicles are involved, can be significant. Paint removal and application, engine and hydraulic system repair and refurbishing, and metalworking (e.g., to repair battle or training damage) involve the use of hazardous substances and result in the generation of hazardous wastes such as solvents, used oils, acids, and plating residues. Repairs and maintenance done in the field can result in localized ecological impacts (oil from a truck released to a stream or onto the ground). It is, however, at the fixed general support or wholesale maintenance centers where the potential for environmental damage is the greatest.

An example of long-term military maintenance activities that affected the environment occurred at Barrel Bluffs at the King Salmon Air Force Base in Alaska 280 miles (450 km) southwest of Anchorage. The approximately 730-acre (295-ha) King Salmon Air Station was built at the beginning of World War II as a military fuel and maintenance facility to help guard the Aleutian Islands. The air station also served as a control and warning site for the air defense system in Alaska during the cold war of the early 1950s as part of the North American Aerospace Defense Command, or NORAD. On the Alaska Peninsula and adjacent to Bristol Bay and Katmai National Park and Preserve, the King Salmon area developed into a major government, transportation, and service center for the commercial red salmon and recreation industries.

The state of Alaska acquired the airfield in 1959, and it now serves as a commercial airport. A massive environmental legacy, however, was left by 20 years of military operations, under close-to-wartime conditions. In addition to an extensive plume of trichloroethylene- (TCE) and petroleum-contaminated groundwater, between the mid-1940s and the mid-1960s, an estimated 500,000 drums of fuel oil, solvent residues, and other wastes generated from maintenance activities were buried in the Barrel Bluff area. Civilian housing was built in the area of Barrel Bluff, but the air force purchased the housing and relocated the residents once the extent of the contamination became known.

From 1996 through 1998, under the oversight of the U.S. Environmental Protection Agency and Alaskan Department of Environmental Conservation, the air force removed most of the near-surface containers. A \$13-million program of recontouring and capping then was initiated along with a long-term operation, monitoring, and maintenance

plan. This long-term plan requires site-access and land-use restrictions, regular inspection and maintenance, and continued operation of water-treatment and groundwater monitoring systems.

### DEVELOPMENT AND TESTING OF MUNITIONS

As the military missions have changed, and as technology has improved, the armed forces' need for a large, widespread infrastructure has significantly decreased. The military bases from which forces are trained, equipped, and deployed play an important role in ensuring mission effectiveness. These military installations and associated weapons ranges, as well as the organization and stationing of its forces, however, are constantly being reevaluated. A key component of that evaluation is BRAC, the Base Realignment and Closure Commission. In 1988, 1991, 1993, and 1995, the Department of Defense (DOD) carried out base realignments and closures through the BRAC process. BRAC allows the DOD to consider changes in threat, force structure, technologies, doctrine, organization, business practices, and plant inventory. The DOD then is able to develop base realignment and closure recommendations in a fair, consistent, and transparent manner. In 2005 alone, BRAC recommended and Congress approved closure of Fort Monmouth, New Jersey; Forts Gillem and McPherson and Naval Air Station Atlanta, Georgia; Fort Monroe, Virginia; U.S. Army Garrison-Selfridge, Michigan; Naval Station-Pascagoula, Mississippi; Naval Station-Ingleside, Naval Air Station-Corpus Christi, and Brooks City-Base, Texas; Onizuka Air Force Station, California; Galena Airport Forward Operation Location, Alaska; and almost 400 Army Reserve and Army National Guard facilities.

Once these facilities are decommissioned, the DOD remains responsible for cleaning up soil and groundwater contamination that may have been caused by their operations. BRAC-closed facilities and other such properties are known as Formerly Used Defense Sites (FUDS). The army manages the program and the U.S. Army Corps of Engineers (USACE) controls and directs related environmental cleanup activities. The scope and magnitude of the FUDS program are significant, with some 9,200 former bases and facilities identified for potential inclusion in the process and 2,700 of those requiring near-term remediation.

One of the major issues facing the FUDS program is the cleanup of environmental contamination associated with conventional military munitions testing and development. Conventional military munitions are those that are not biological or chemical agents

or nuclear/radioactive in nature. The firing of small arms can contaminate the ground with lead, and propellants and pyrotechnics from projectiles can leach heavy metals and organic chemicals into the soil and groundwater at launch and impact sites. Finally, the on-site disposal of UXO (unexploded ordnance) through burial or inefficient and often incomplete open burning/open detonation can result in both an explosive hazard and ecological damage. The following table describes some of the most common military munitions and their related environmental and health effects.

### Production Facilities

At the Badger Army Ammunition Plant in Sauk County, Wisconsin, single- and double-base propellant for cannon, rocket, and small arms ammunition was manufactured intermittently for more than 30 years. Double-base propellants consist mainly of fibrous nitrocellulose and a gelatinizer, or plasticizer, such as nitroglycerin or a similar compound (ethylene glycol dinitrate). Each base contains two active ingredients, oxygen and fuel, in the same compound. Single-base propellants are smokeless powders utilizing either nitrocellulose (gun cotton) or nitroglycerin as the only active constituent.

At the time it opened at the beginning of World War II, Badger was the largest propellant manufacturing facility in the world. Employing more than 20,000 people, the plant operated around the clock and included housing, schools, and recreation facilities for workers, many of whom spent the entire war years living on its secured grounds. Placed on standby status at the end of the war, Badger was reactivated for the Korean and Vietnam conflicts. In 1997, Badger was declared surplus property and permanent decommissioning activities began.

Facility operations resulted in extensive soil and groundwater contamination. In the late 1990s, 1 million pounds (453,592 kg) of leftover nitrocellulose was converted to fertilizer and then was applied to land to be used for livestock grazing and farming. The former open burning site at Badger was closed with soil cover in 1996. Groundwater treatment facilities treating 3,400 gallons (12,870 L) of water per minute are addressing the contamination. The treated water is being used at Badger for all water not suitable for drinking. In 1997, a former landfill was closed with a cap and a soil vapor extraction system.

As required by an RCRA Corrective Action order, environmental scientists identified 312 areas within the plant grounds that had been contaminated. The cost of the investigation and remediation is in the range of \$250 million. Solvents (carbon tetrachloride and TCE), metals (lead), and explosive wastes

**EXPLOSIVES GLOSSARY**

Type	Definition	Example
Low-Order Explosive	Produce a subsonic shock wave and almost no pressure wave. They tend to burn rather than explode.	Gunpowder, flares, pyrotechnics (fireworks), and petroleum-based bombs such as Molotov cocktails
High-Order Explosive (High Explosive)	Produces a high-speed shock wave that has a powerful blast effect. During detonation, the high explosive is decomposed into hot, rapidly expanding gas.	Nitroglycerin: a primary explosive that can detonate with little or no stimulus. Dynamite (trinitrotoluene or TNT): a secondary explosive that requires a strong shock (from a blasting cap) to detonate. Secondary explosives can be further subdivided into "melt-pour" explosives, which are based on nitroaromatics (TNT), and "plastic-bonded" explosives, which use a binder and crystalline explosive (RDX)
Blasting Agents (Tertiary Explosives)	Very insensitive to shock. Require an intermediate (secondary) explosive booster to initiate detonation	Ammonium nitrate/fuel oil mixture (ANFO) or "wet bag" explosives: used primarily in mining and construction.
Fuse	Simple detonating device that, when ignited, burns slowly and steadily from one end through an opening into the container, where it detonates the explosive charge.	On a firecracker, tissue paper extending from one end and rolled to keep the black powder in its center.
Fuze	Used in military-type munitions to detonate the explosive charge under specified conditions.	Time fuzes, contact fuzes (explode on impact or when stepped on or rolled over), proximity fuzes (activated by radar or sonar), remote fuzes (detonation initiated by an electrical impulse over a wire or by a radio wave).

**COMMON EXPLOSIVES**

Semtex	A type of general-purpose plastic explosive (mixture of RDX and PETN) that is usable over a large temperature range. Used primarily in commercial blasting. Favored by terrorists because it was easy to obtain and difficult to detect, until a special tracer chemical was added so that bomb-sniffing machines could more easily identify its presence. The government of the Czech Republic, where Semtex was developed and currently is being manufactured, controls all current sales.
C-4	Also called Composition-4, it is formed by mixing RDX in slurry form with a binder and allowing it to dry. It forms an off-white solid with a texture like that of modeling clay. It can be pressed into any desired shape and is extremely stable, requiring a blasting cap for detonation.
PETN	Pentaerythritol tetranitrate, used extensively as a military demolition charge, is one of the most powerful high explosives ever developed. When mixed with TNT, 0.5 pound (0.23 kg) can penetrate up to five inches (12.7 cm) of armor plating. PETN also is used as a vasodilator in the treatment of heart disease.
TNT	Trinitrotoluene was developed in the 1860s and is less powerful and more difficult to detonate than modern explosives. Its main advantage is that it can be melted safely using steam or hot water and poured into shell casings or other containers. TNT is very toxic and a possible human carcinogen. Exposed individuals suffer from abnormal liver function and severe skin irritation.
HMX	A plastic-bonded high-molecular-weight explosive exclusively used by the military in both tactical applications and initiation (detonation) of nuclear weapons. It also has been used as a solid rocket booster.
RDX	Research Department (composition) X is a nitroamine-based explosive with a wide variety of commercial and military uses. RDX usually is mixed with a plasticizer and serves as the basis or main ingredient for other types of explosives.

(2,4- and 2,6-dinitrotoluene, nitrates) entered soil and groundwater beneath the plant, especially in an area known as the Propellant and Deterrent Burning Grounds. These were areas where excess, surplus, or off-spec gunpowder and their ingredients were ignited to stabilize and safely dispose of them. The combustion process, however, was often incomplete, and residues remained at the surface or were covered with fill. Rainwater or snowmelt migrating through the chemical residues generated leachate, which subsequently contaminated underlying soil and groundwater.

A three-mile- (4.8-km-) long plume of contaminated groundwater migrated off-site from the Propellant and Deterrent Burning Areas and impacted local private drinking water wells. A soil vapor extraction system was installed to remove volatile organic compound (VOCs) in the subsurface. A 3,000-gallon-per-minute (11,356 Lpm) pump-and-treat system that eventually was installed captured the contaminated groundwater moving off-site and treated it to drinking water quality standard by using a combination of air stripping and carbon filtration. Monitoring data for both systems indicate high removals of VOCs from subsurface soils and groundwater and decreasing contaminant concentrations in source areas.

### Testing Ranges

The Jefferson Proving Ground (JPG) in southeastern Indiana is an approximately 55,000-acre (22,258-ha) army-run facility opened in 1940 that is about eight miles (12.9 km) north of the Indiana-Kentucky border. Until 1995, JPG tested ammunition and related weaponry. Declared by BRAC no longer necessary, JPG was closed, and in 1996 decommissioning (removal of UXO) and environmental cleanup began. When operations ceased, JPG contained almost 380 buildings, more than 180 miles (290 km) of roads, 50 miles (80.5 km) of boundary fence, and an abandoned airport with four runways.

An east-west, 268 former gun position firing line divided the base into a 51,000-acre (20,639-ha) Northern Firing Range Area and a 4,000-acre (1,619-ha) Southern Cantonment Area. The cantonment area was used for administrative support, ammunition assembly and testing, vehicle maintenance, and temporary housing of troops. As in any industrial facility in use at the time, the soil and groundwater within the cantonment area have been affected by the spillage and disposal of polychlorinated biphenyls (PCBs), petroleum hydrocarbons from underground storage tanks (USTs), cleaning solvents, and heavy metals, primarily “red lead” used as a propellant oxidant. The wastes were emptied

into pits, spread out on the ground, open-burned in designated areas, or buried in one of several on-site landfills. Proposed cleanup activities for these wastes include limited removal, institutional controls based on future anticipated commercial/industrial land use, and continued long-term monitoring.

The northern area consists of undeveloped and heavily wooded land. It was into this part of the base that more than 25 million projectiles and explosive charges were launched, and it contains numerous discrete clearings that were targeted during munitions tests. The army estimates that up to 1.5 million fragments of UXO, including 150,000 pounds (68,039 kg) of depleted uranium, may still be present within the Northern Firing Range. Only slightly radioactive, depleted uranium remains after the fissionable isotopes (U-234 and U-235) were removed for use in weapons or reactors. The very dense, depleted uranium was used in projectiles and other weapons to penetrate armor.

The army has removed some depleted uranium and other UXO residues from the northern area but is still developing plans for a complete cleanup. Limited access to this area for hunting and fishing, as well as its use by a local Native American tribe, have been granted, and its use as a recreational and wildlife resource is expected to expand as cleanup activities move forward.

### LAND USE

The DOD is one of the largest landowners, responsible for more than 450 major installations that utilize greater than 25 million acres (10.1 million ha) of land. These bases often have significant effects on the land they occupy. Environmental impacts associated with their respective missions, however, can include damage to local, sensitive, or specialized ecological areas, particularly wetlands. Training areas must provide a realistic experience so that troops and equipment can be tested and acclimated to all types of terrains, including swamps, marshes, permafrost, and coastal areas. The movement of heavy equipment and personnel through such sensitive ecological zones, as well as use of ordnance, often results in significant disruption to habitat. The military now attempts to conserve the land on its bases and host communities. For example, the Pinon Canyon Training Area, Colorado, operates on a two-year rest and rotation schedule for 25 training subunits. No more than 50 percent of the total land is in use at any time. This “rest and rotation” cycle allows environmental recovery of the area between exercises.

These types of land use impacts are usually local and take place well within the confines of most military

bases. The loss of a few tens of acres of wetlands is deemed a reasonable environmental price to pay for a well-trained military force. Critics of these practices maintain that the military disregards the long-term land use. As an example, the island of Vieques just off the coast of Puerto Rico was purchased by the U.S. Navy during World War II and managed as an extension of the Roosevelt Roads Naval Base on the nearby Puerto Rican mainland. For almost 60 years, the eastern tip of the 52-square-mile (135-km<sup>2</sup>) sparsely populated island served as a testing and training ground for bombs and missiles. In the early 1990s, concerned about contamination from the bombing, as well as a high cancer rate among island residents, community leaders on mainland Puerto Rico joined with native Viequians and began to question the need for continued weapons testing on the island. The navy did not respond well, and the questions turned to protests leading to acts of civil disobedience by the late 1990s that interfered with naval operations. Blockades of U.S. Navy warships by local fishing vessels and the regular occupation of bombing ranges by thousands of protestors, some of whom were government officials, union leaders, clergy, actors, and other prominent public people, led to widespread international media coverage.

By 2003, the navy agreed to cease operations on Vieques and turn over its land to the government of Puerto Rico. The bombing ranges were assigned to the U.S. Fish and Wildlife Service for management and decontamination. In 2004, the navy closed Roosevelt Roads. Similar, although much smaller scale land use protests have taken place at Culebra, Puerto Rico, and Kahoolawe, Hawaii.

The U.S. military must also deal with encroachment of private development around its active bases. Residential and commercial development around military facilities can lead to significant restrictions on an installation's mission or even result in its closure. As homes and businesses encroach a base perimeter, civilians can be exposed to the noise, dust, explosive residues, and other environmental consequences related to operations. To ensure that military installations are able to function in a manner consistent with their mission, a number of states and municipalities are addressing encroachment issues. In states with a significant military presence such as Virginia and Texas, legislation has been drafted that requires compatible land use. Some states have created advisory boards to help towns and cities plan development that is supportive of a base's mission.

In other states such as Arizona and California, the region around some military bases has been declared

"areas of critical state concern," and special land use restrictions have been imposed to protect the integrity of the installation's activities. The military also has recognized the dangers of civilian encroachment and usually works with a community when these concerns begin to develop. In some cases, flight paths have been changed to help mitigate noise, and night training exercises are relocated or eliminated. The intent of these actions is not to stop local development, but to organize it in a way that allows the local community to maximize the benefits of hosting a military presence.

**mining and pollution** Although they are very small and localized sources of pollution, mines and mineral processors are among the most damaging activities to the environment. They can destroy ecosystems and render otherwise productive

areas completely devoid of life. Recovery of these areas can take centuries by natural processes, and, even then, there can still be repercussions. Some examples of the most devastating pollution result from mining, smelting, and processing operations. According to the United States Geological Survey, total domestic mining and waste removal for non-fuel mineral materials production at underground operations amounted to 162 million tons (147 million metric tons) in 2006, and crude ore mined at these underground operations was 158 million tons (144 million metric tons). The balance was ore and waste from development. Total underground mining for industrial minerals amounted to 142 million tons (129 million metric tons), nearly all of which was crude ore. Underground mining for metal ores amounted to only 21 million tons (19 million metric tons), of which 84 percent was crude ore. On a global scale, Stavros Dimas, the European Union commissioner for environment, states that “waste from extractive operations . . . is one of the largest waste streams in the EU.” The vast amount of mining and ore processing conducted in the United States has left an environmental legacy that the Federal Bureau of Land Management has called “substantial.” These wastes include contaminated and acidic water, waste rock and tailings, leaks from chemicals stored at mine sites, and damage to vegetation and wildlife from particulate air pollution (fallout) emitted during mining.

### BASICS OF MINE POLLUTION
